LECTURES
ON THE
CHEMICAL HISTORY, PATHOLOGY, AND
MEDICAL TREATMENT
OF
CALCULUS,
AND THE VARIOUS DISORDERS OF THE
URINARY SYSTEM.

By DR. VENABLES.

Diuresis ureosa.—The peculiar feature in this form of urinary disease is, the excess of a natural principle of urea, and which sometimes exists in such superabundance as can scarcely be well accounted for. It often happens that an excess of urea is to be detected in the urine from mere accidental circumstances, as, for instance, in certain febrile states, and inflammatory diseases. But in such cases the excess seems to be only relative, not absolute. These conditions reduce the watery portion of the urine, while the solid matters are natural, and consequently an excess of urea is indicated on examination by tests. But in the affection we are about to consider, not only is the urea in excess, but this is associated with distinct diuresis. Indeed, the general symptoms so completely resemble those of *diabetes mellitus*, the affection we have next to consider, that there can be no doubt the former has often been mistaken for the latter disease.

The general symptoms of this disease are, thirst, increased appetite, and a harsh, dry, or unperspirable state of skin. These symptoms, however, do not in general prevail to such an extent as to be very remarkable, except in extreme cases, or when the urea alternates with that which characterizes the next form, namely, sugar;

as we shall soon have occasion to illustrate. In all the cases which I have seen there has been a frequent and very urgent, indeed an irresistible desire of passing the urine, and this propensity exists both night and day. The frequent desire to evacuate the bladder leads to the confounding this disease with others in which this latter symptom is a predominant character. Thus I have known instances in which this affection is regarded and treated as stone in the bladder, at least so far as sounding, &c., and for other morbid affections of the bladder.

The frequent desire of passing the urine is often accompanied with pains in the loins, sometimes of a subacute, sometimes of a dull character; sometimes a mere sense of weight, and in some cases there is no feeling at all of this description. There is generally some irritation about the neck of the bladder, and this extends itself along the whole course of the urethra, giving rise to a sense of smarting or itching, short of pain, during the passage of the urine.

The vital functions seem to suffer but little at the beginning of this complaint; hence we find the pulse and respiration but little involved. With respect to the animal functions, a degree of languor and a feeling of lassitude frequently prevail; and there is often some degree of listlessness, so that the patient, once at rest, will not be readily aroused or easily excited to vigorous exertion; but once excited, he seems capable of the ordinary activity. The stomach and bowels are not much distended; however, there is, if any thing, a tendency to tardiness of action in evacuating the contents of the alimentary canal. The tongue is, for the most part, clean and moist.

There is, for the most part, an increased flow of urine, although the quantity passed at once is often greatly below the natural quantity, so that the diuresis rather de-

pend upon extraordinary frequency of evacuation than upon an increased flow at any one time. Yet I have frequently seen instances in which not only the frequent desire to evacuate the bladder was urgent, but a considerable quantity voided at each call, so that in such instances from ten to twenty pints of urine have been voided in the twenty-four hours. Such is a general view of the history of this affection.

Causes.—With respect to the causes, they are unquestionably very varied in their nature. The predisposing may be considered all which tend to debilitate the system generally, and the urinary organs in particular. Various abuses of the constitution, and especially an indulgence in a particular abuse of the generative functions, may, and frequently do, give rise to this form of disease. Dr. Prout remarks, "In most of the cases of this disease which have fallen under my own immediate observation, the subjects have been middle-aged men of thin and spare habits, with a sort of hollow-eyed anxiety of expression in their countenance; free from gout and constitutional disease in general, and as far as could be ascertained, from any organic defect in the urinary organs. In every instance they had been induced to apply for medical advice, not so much from the pain as from the inconvenience of the disease, and the dread of its ending in something worse; and what may be worth remarking in several instances, confessed that they had been addicted to *masturbation* from early youth*." These are features which subsequent experience have most amply confirmed. I myself had an opportunity of seeing this peculiar expression of countenance in a gentleman residing in Essex, and who was seen subsequently by Dr. Prout. The eyes were sunk, as it were, in the orbits, and indeed gave a most peculiar expression to the whole countenance.

Dr. Prout does not mention females as the subjects of this disease; but I have seen several instances of this affection in women; and in two cases of diabetes in women, from the history I have not the slightest doubt that an excess of urea in the urine must have preceded, and subsequently alternated with sugar, previous to the fixed and invariable presence of the latter principle.

Immediate cause.—There is little to be said upon this head; it must be evident that urea in excess in the urine is the immediate source of the disease, although we shall presently have occasion to shew that an excess of urea may be present, without the presence of the disease we are attempt-

ing to characterize; and the great peculiarity of which is, its almost certain termination in diabetes, if not controlled. With respect to the morbid anatomy there is nothing to offer. The disease does not of itself prove fatal, and therefore we do not have opportunities of examining the conditions of the urinary organs till other forms of disease have supervened, and which put a period to existence. It may, however, be stated, that there unquestionably seems to be in many instances a peculiar irritability of the bladder, and, indeed, in not a few, the prostate gland seems thickened, indurated, or otherwise morbidly affected.

Diagnosis.—This, perhaps, may seem almost a superfluous consideration, because the only thing to be determined would, at the first, appear to be the excess of urea. But urea appears in excess, as has been already stated, under a great variety of even dissimilar circumstances. Therefore it will be necessary, an excess of urea existing, to determine whether this is connected with the disease under our special consideration.

First, therefore, we have to determine the presence of urea in excess; and this is readily done by the addition of nitric acid. The best method of proceeding is to pour a little of the urine to be examined into a glass capsule—a watch glass answers every purpose—and with a fine-pointed tube, blown with a bulb in the centre, take up a quantity of nitric acid, and allow this to flow slowly, in the manner you now see me do, along the concavity of the glass. The acid, as you observe, from its superior gravity seeks the bottom, and floats the urine upon its surface, and in a time proportioned to the excess, crystallization commences. In the present instance it will take from twenty minutes to half an hour; but there are instances in which crystals form within almost as many seconds, and the time within which crystallization takes place is a tolerably accurate though not unerring index of the excess. The urea, on crystallizing, assumes a great variety of appearances: sometimes the crystals appear silky or pearly, and almost colourless; in other cases they are more deeply coloured, and present an irregularly radiated or confused mass; in some they present a conical appearance, the base presenting a convex circular margin, the apex presenting to the centre of the glass: in a word, they closely resemble the papillæ of the kidneys, and, indeed, the whole figure of the tubular structure of the kidneys. In the ten specimens which I here present you perceive great variety in the mode of crystallization, and the differences are to be recognized by observation rather than by

* On the Urinary Organs, p. 53.

any verbal descriptions, which, in relation to sensible properties, are very often incomprehensible and unsatisfactory.

To determine, then, the peculiarity of excess which we are considering, we must connect this with the other phenomena. In the disease in question there is for the most part a desire of frequently emptying the bladder. This occurs, although the quantity of urine voided does not amount even to the quantity voided in a state of health. The case to which I have already alluded, and in which I had the assistance of Dr. Prout, was thus afflicted. The calls were so frequent and so urgent, that the gentleman told me that in a journey of about eight or ten miles, which he had frequently to perform, he was often obliged to get out of his chaise eight or ten times, or even oftener, to satisfy the urgency of the call to evacuate the bladder. The sensible qualities of the urine, too, are often indicative of the nature of the affection. The urine, I think, for the most part is of a bright red colour, somewhat like ale, and, indeed, as far as my experience goes, ale affords the best example of the colour; but under certain circumstances, particularly a principal meal, especially where animal food has been used, the colour is darker, and resembles porter diluted with water in various proportions*. The taste is usually saline and bitter, and the smell aromatic, and sometimes resinous. The specific gravity is always high: it sometimes happens that urine of low specific gravity, viz. 1008-1013, indicate, with nitric acid, an excess of urea; but these cases are of a very different character, as we shall shew hereafter. In the present affection, however, the specific gravity varies between 1020 and 1027: it is seldom much higher or lower, unless from the agency of foreign causes—medical treatment, dilution, diet, &c. You here see a specimen of the urine of a person who I strongly suspect labours under this affection. In this case the specific gravity was 1024.811; when I last saw the case, about three days ago, the urine, which I then examined, was 1024.95; and if you examine the history of the cases published, you will find the specific gravity to range to somewhat between 1020 and 1030; but when it arrives at the latter degree, I think, if you examine closely and attentively, you will find either the co-existence of sugar in small quantity, or the alternation of these principles with some modification of the sensible characters—for instance, of the ale or porter colour; the urine will be either of a pale straw or a sort of *greenish blue*, as will be hereafter described. What

we have just stated will be quite sufficient in most cases to detect the nature of this affection; an object which, if of no other advantage, is useful to prevent us falling into errors, and deceiving others, by naming diseases of a very different complexion *diabetes*, or even considering them as the first step to this affection.

Pathology.—The difficulty of explaining, at least satisfactorily explaining, the source of urea in the urine, renders the pathology of the disease under investigation no less difficult. Indeed, could we even explain the appearance of urea in the healthy ratio, yet we should still have great difficulty in explaining the increase, especially as a precursor of diabetes. Why an excess of urea, a principle which contains so much nitrogen in its composition, should be in any way connected with, or influenced by, the appearance of a principle which contains no nitrogen whatever, is certainly one of the most extraordinary problems, as well as one the most difficult of solution, in pathology. I fear, therefore, it will be necessary to pass over this question without entering deeper into the subject than we have already done. But still there are some other points that we may readily explain, and which, as presenting in part diagnostic characters, it is as well to understand.

It has been already stated that an irresistible propensity to pass the urine co-exists with this affection. Now, upon what does this propensity depend? Not upon an excessive and rapidly supervening fulness of the bladder, because the quantity of urine voided at each time often falls short of the natural proportion; and in the case which I have already referred to, and some others of a similar description which have since come under my observation, the urine voided at each call fell very much short of the natural quantity. This is sometimes so much the case as to have given rise to the idea of stone in the bladder, ischuria, &c. The gentleman to whom I have alluded frequently would not pass one or two ounces at each micturition, and sometimes even not more than a tablespoonful. Neither does the urgency appear to depend upon any acrimony of the urine itself; for the presence of urea in excess does not appear of itself to produce any sense or consequence of acidity, for in other instances urine loaded with urea has been retained in the bladder without any inconvenience. Therefore we must look to the bladder itself, or to some morbid condition of it, for an explanation of the tendency to preternatural uresis. There can be little doubt of an extremely irritable state of the bladder in such cases, and this condition is the source or cause of the unnatural propensity. In such cases,

* Prout on the Urinary Organs, p. 32.

too, we often find a diseased state of the prostate, and almost invariably the presence of hæmorrhoids. Now these are almost, indeed quite sufficient of themselves to account for an irritable state of bladder; and the abundant mucous cloud which in time is deposited by such urine, proves almost unequivocally the excited or irritable state of the mucous lining of the bladder and urethra. In many cases, too, if this cloud be examined by the microscope, the squamulæ already noticed are found in excessive quantity, and which you may here observe on looking through this microscope.

When, too, we reflect on the causes, we shall find that many of them operate in such a manner. The patient at the commencement is harassed by the incessant calls to evacuate his bladder; he imagines stricture, stone, and a number of other such affections: hence he subjects himself to the introduction of catheters, bougies, sounds, &c., and thus often through imprudence brings on many of the evils the presence of which he is merely attempting to ascertain. Perhaps there is no cause which more speedily or more effectually gives rise to urinary irritation than maltreated gonorrhœa. The irritation arising from the application of the various stimulating and astringent agents, so frequently resorted to for the speedy suppression of this affection, leads to evils and consequences the connexion of which are not perceived, because they occur at distant and remote periods—when the origin, perhaps, has been wholly forgotten. Thus cubebæ, turpentine, cantharides, and the whole host of astringents employed by the impatient, not only disappoint expectation, but often lay the foundation of severe and obstinate—often fatal—diseases. From their irritation, however, we can easily conceive a permanent irritability of the urinary system generated, and which, though it may lie dormant during the vigour of youth, will yet be transmitted to a period of life when it will shew itself with increased and even irresistible violence, sowing the seeds of the most distressing and incurable maladies, and which the unhappy sufferer at length discovers with the melancholy certainty that he is doomed in future to a miserable existence, and to endure all the calamities of the most obdurate and incurable diseases. But much as has been effected in the development and elucidation of these affections, there is still ample room left for investigation, and we may apply here with great truth the words of Seneca:—*“Multum egerunt qui ante nos fuerunt, sed non peregerunt, multum adhuc restat operis, multumque restabit, nec ulli post*

mille annos nato præcludetur occasio aliquid adjuvendi.”

Prognosis.—An excess of urea, as we shall hereafter see, is associated with a number of affections differing very much in their character; but the disease under consideration has this peculiarity, that it is for the most part the precursor of diabetes. Diabetes is now pretty generally admitted to be an incurable disease; and if the antecedent were equally intractable and incurable, we could hold out but a very melancholy prospect. However, we have a very consoling reflection in the observations of Dr. Prout, who states that this complaint has often been mistaken for diabetes; “but it differs,” he says, “from diabetes, in being a curable disease, or at least, by care and attention, it can be so far subdued as to be rendered little troublesome.” But notwithstanding the high authority of Dr. Prout, I should recommend a cautious prognosis; not that I entertain the slightest doubt of the correctness of the Doctor's statement; but to insure so satisfactory a result requires many and great sacrifices, and which, by those who have indulged, are looked upon not only as severe, but unnecessary sacrifices, and which, if we hold out a favourable prospect upon too easy terms, few will endure. We may lay it down, therefore, that by great care and attention, especially to diet and regimen, and a judicious treatment, the disease, if it have originated in accidental causes, may be wholly eradicated; but if there be an hereditary tendency to diabetes, we may consider ourselves but too fortunate if we can keep the disease in check, and prevent the diabetic diathesis being irremediably established.

Treatment.—There is so little known as to the manner in which the urinary functions are performed, that we can infer but little certain of the method of correcting their errors. We know that urea is formed in the urine, but how it gets there—how it is generated—as yet we know but little. It has been found in the blood, but still this does not remove our difficulties, because it has not been found uniformly in the blood. If the blood invariably contained urea, we should have little difficulty in understanding the operation of the kidneys, viz. that the urea passed out of the system through these organs. But as this principle only appears under a suspension of the renal functions, we are at a loss to understand how urea appears abundantly in the one, and leaves not a trace of its existence in the other. All perhaps that we can legitimately infer, therefore, is that the loss of the kidneys leaves the circulating mass

in a condition favourable to the generation of urea, and that, too, in sufficient quantity to appear uniformly diffused throughout the blood. Consequently it cannot be wondered at that a disease, the nature of which is involved in so much obscurity, does not, in the present state of our knowledge, admit of any thing like a method of cure founded upon philosophical principles. There is one circumstance, however, that we should keep in view, namely, the tendency to run into or terminate in diabetes. Dr. Prout, who first suggested these views, seems to have been since confirmed in the reality of his conjecture. "I have had no opportunity," he says, "of ascertaining the progress of these diseases; but think it extremely probable that, if permitted to proceed, some of them will terminate in diabetes, or in a deposition of the earthy phosphates*." Therefore the great object will be to prevent this affection from running into diabetes, which is an incurable disease. An object of primary importance is, therefore, to correct all irregularity in the functions of the digestive system, and to improve the general health and strength. After what has been already stated, it would be quite superfluous to enter a second time upon these principles of therapeutics. The digestive functions having been properly regulated, our next object should be to control the errors in the urinary excretion. Astringents, therefore, naturally present themselves as indicated in these circumstances.

Of the astringent remedies, opium certainly has obtained the highest reputation. "In most of the cases, however," says Prout, "which have hitherto fallen under my own observation or knowledge, sedatives, and particularly opium, have been the most efficient remedies; and by the judicious use of these, combined with other appropriate medicines, it is probable that in most instances the disease can be suspended, if not removed altogether†." Opium may be given under any of the usual forms. The *pilula saponis cum opio* of the London Pharmacopœia is a very excellent preparation, and often well adapted for exhibition in cases of this nature. Of this preparation five grains may be given once, twice, thrice, or even four times in the day, according to the urgencies of the case. It has, however, been stated, that the functions of the skin are often suppressed; and in such cases those preparations which more effectually excite the action of this organ, prove equally, if not more effectual. Hence the compound powder of *ipeacacuanha* presents a very effectual

preparation of opium. In one of the cases related by Dr. Prout, in consequence of some biliary derangements, after alterative doses of mercury with purgatives, the urinary part of the complaint gave way to a bitter infusion, containing potash and opium. The amendment was indicated by the reduced specific gravity of the urine from 1023·7 to 1015·5, and in the quantity of urea being greatly diminished. The disease was never completely eradicated, and used to return at intervals, especially during the time when, from cold, the action of the skin was interrupted. When, however, it returned, it was generally relieved by the use of soda-water and tincture of opium, in the proportion of ten or twelve drops of the latter to a glass of the former*. However, the Doctor also states, that although the urine in this case had much improved, it never became quite natural, either in appearance or in the proportion of urea; and I believe, generally speaking, this will be as much good as can be generally expected. Indeed, under every mode of treatment, it mostly happens that the disease returns with its usual violence, at intervals, owing probably to the impossibility of regulating life upon fixed and inviolate rules.

In the case which I have alluded to, although under the treatment adopted, the gentleman's health, and even the complaint, were considerably ameliorated, yet the disease returned, with all its pristine violence, at intervals; although, by an unusual degree of strictness, the symptoms again improved, and the patient enjoyed a tolerable degree of immunity. Dr. Prout ordered for this gentleman a combination of the compound powder of *ipeacacuanha* with the acetic extract of *colchicum*, in the proportion of one drachm of the former to one scruple of the latter, the whole divided into twenty pills, of which the patient took one twice in the twenty-four hours. The disease gave way very much under this plan of treatment with castor oil, as he was subject to hæmorrhoids, to keep the bowels open. He could now perform the journey from his own residence to Chelmsford, about ten or twelve miles, with but one or two calls to evacuate the bladder; whereas, previously, from twelve to fourteen or sixteen were the average number.

Subsequently, however, the *ipeacacuanha* and opium were in some degree modified, the sulphate of morphia having been substituted for the opium, in the Dover's powder. About a grain of the sulphate was accurately mixed and rubbed with an equal quantity of *ipeacacuanha* and eight

* On the Urinary Organs, p. 54.

† Ibid.

* On the Urinary Organs, p. 56,

grains of sulphate of potass and the extract of colchicum, as before stated. If this should not readily form a pill mass, a little extract of hyoseyamus will give the requisite consistence.

I have, in several instances of this sort which have come under observation, directed a combination of kino and opium, and certainly with a very considerable reduction of the urea. The very last case which came before me was treated with kino and opium, and a mixture containing tincture of catechu and wine of colchicum, and certainly with very beneficial results; but the good obtained was in some measure marred by the constipation of bowels which the combination of so many powerful astringents produced. When the prostate gland seems affected, leeches and the various other means of relieving the local affection should be resorted to, and they are already too well known to be specifically alluded to here.

It has been already observed that there exists, in many cases, a peculiar irritability of bladder, and which frequently urges to almost incessant evacuations of the bladders. This is attended with very great inconvenience, and, indeed, is to the patient the only distressing part of his complaint. Means, therefore, of reducing or of counteracting the urgency of these calls, are matter of great moment. They are found to be much aggravated by every thing which increases the urine or renders it more stimulating: hence by certain liquors and green tea. The state of the skin, too,—for instance, constriction from exposure to a cool atmosphere, is found to augment the urinary discharge. Hence the former should be avoided, and the warmth of the latter kept up by sufficient clothing, especially of flannel. To relieve the bladder, some bland fluid should be given; and I found nothing so effectual as the *mistura amygdalæ*, which may be given in doses of one or two ounces, three or four times in the day. By these means you will find, unless in very obstinate cases, that the symptoms will abate, and the urine improve and become more natural. Alternatives, if indicated, are not objectionable, but in most cases in which there is an excess of urea, mercury in large quantity is injurious, or at least the propriety of the practice is questionable. These means should be persevered in till the requisite improvement has been obtained, and even the liability to a return of all the most urgent symptoms naturally suggests the propriety of not wholly laying aside these measures, but that we should occasionally resort to them to prevent relapse.

When the urinary functions have been properly restored, then, tonics will be ad-

visable, for the purpose of strengthening the constitution generally. In some cases quinine has answered very well; but in general the minerals, especially iron—as the phosphate, sesquichloride, &c. answer; but these will be considered more at length when we come to diabetes.

CLINICAL LECTURES,

Delivered in Jervis-Street Hospital, Dublin,

BY DR. CORRIGAN.

Session of 1838-9.

Paralysis of the first and second Branches of the Sensific Root of the Fifth pair of Nerves; Case of Goulding.—Anatomy of the Fifth pair of Nerves.—Application of it to Diagnosis of the Case.—Paralysis of the Portio Dura.—Paralysis of the third Branch of Fifth.—Paralysis of Fifth and Seventh combined.—Classification of Paralytic Affections of the Face.—Treatment and Recovery of Goulding.

CASE.—Catherine Goulding, æt. 23, was admitted into hospital 24th October, 1838. Six months before this date, she fell on her temple against an iron grate, and at the time felt a very acute pain in the part, with numbness in the left side of the head and face. The pain having continued, and her sight in the left eye having grown dim, she took some purgative medicine, and after this she continued pretty well until about two months before admission, when the pain of the temple returned, followed by almost total loss of vision in left eye. On admission, almost total loss of sight in left eye, with a very sluggish iris, a clear and a dilated pupil. She suffered from thirst, loss of appetite, and debility. Her bowels were confined; her tongue was white. The treatment adopted was leeching the temples, blisters to the back of the neck, and mercury pushed to active salivation. These measures greatly alleviated her symptoms, but on the 8th November there was a return of the pain in the temple, with dimness of vision, and followed on the succeeding days by tingling and numbness in the left side of the head, and extending down the face. A blister to the side of the head alleviated these symptoms, and the sight of the left eye continued to improve, but the numbness of face increased; and on the 10th December the following is the report of her state:—

She is slightly salivated (she had been using gr. iij. of *pilula hydrargyri ter in die*). Over the left side of the scalp and in the ear there is undiminished sensibility, as also in all the portion of the cheek, which is below a line drawn from

the angle of the mouth to the lobe of the ear. But in the left half of the forehead, the left eyebrow, around the left eye, and in the anterior part of the left cheek, and in the left half of the nose within and without, and in the left half of the upper lip, there is total loss of sensation; so that in any of those parts the skin may be pricked with a needle without her being conscious of it. In the left half of the upper gum there is also total loss of sensation. In the lower gum the sensation is duller than natural. There is no loss of muscular power in the jaw or eyelid, nor any appearance of paralysis either when the face is at rest or when she speaks. In the left temple there was a circumscribed spot, which was very painful on pressure, and which, when pressed upon, gave her a shooting pain down the cheek. Over this spot she was leeches every second day. Her sight improved, the pupil became more active, but the other symptoms remained as before, with the addition that on the 21st December she complained of inability to move the jaw freely on the left side. There is, however, no want of power in the left eyelid. The repeated leeching has diminished the soreness of the temple and improved the sight very much, and she is now rubbing the scalp with tartarized antimony and mercurial ointment, and taking internally 10 grs. of hyd. c. magnesia ter in die.

This case is a valuable addition to our knowledge of the affections of the nerves of the face, which, until late years, was little better than a web of confusion. To Sir Charles Bell we owe the first clue that has led us out of the labyrinth; and the case before us, of Goulding, deserves a place among those to which we may refer as establishing the sureness of the foundation on which our opinions of the functions of the nerves of the face now rest.

To understand the nature of Goulding's case, it is necessary to recal your attention to the anatomy of the fifth pair of nerves. There is in this case total loss of sensibility of the left side of the forehead, of the left side of the nose, of the left side of the palate, and of the gum of the left half of the upper-jaw, and of the upper-jaw, and of the cheek, as low as the angle of the mouth; while, below a line extending from the angle of the mouth to the lobe of the ear on the same cheek, the sensibility is perfect. There is not the slightest loss of muscular power in any part of the cheek; she has full power over the eyelid, angle of the mouth, buccinator muscles, &c. whether in chewing, sucking, laughing, &c.

The anatomy of the fifth pair of nerves will now explain to us this case, which is

one of those beautiful instances in which anatomy, physiology, and pathology, mutually throw light on each other. The fifth pair of nerves consist, you will recollect, of two roots; one the sensitive—the other the motor root. The sensitive root, after having formed upon it the Casserian ganglion within the skull, sends off from this ganglion three branches; the first the ophthalmic branch, which is distributed to the parts within the orbit, and which sends off the supra-orbital branches to the skin and integuments of the forehead, with a brush of smaller twigs which are distributed over the inner canthus of the eye and the root of the nose, while the nasal branch is spread over the alæ and tip of the nose. The second branch, the superior maxillary, given off from the Casserian ganglion, leaves the skull through the foramen rotundum, and sends along the infra-orbital canal, in the floor of the orbit—the infra-orbital branch, which passing out to the cheek through the infra-orbital foramen, is then distributed to the anterior part of the cheek to the ala nasi, and twigs of it descend as low as the external angle of the mouth; where they meet those coming up from the foramen mentale. Other twigs of this second branch, the superior maxillary, are distributed to the palate, the gum of the upper jaw, and the interior of the nose.

I have now to turn your attention to the third branch of this sensitive root of the fifth. This branch, setting out also from the Casserian ganglion, leaves the skull by the foramen ovale, in company with the motor root of the fifth pair. This motor root, which has lain in the skull behind the Casserian ganglion, has as yet formed no junction with any portion of the sensitive root; but having passed out through the foramen ovale, in company with the third branch, it then, in the pterygoid fossa, becomes intimately interwoven with this third branch of the sensitive root, and the compound nerve, thus formed, is the inferior maxillary nerve. It is obvious that, according to this account of the anatomy of the fifth pair of nerves, the ophthalmic and superior maxillary nerves being given off by the sensitive root of the fifth before any connexion has as yet taken place between the sensitive root and the motor root, the ophthalmic and superior maxillary nerves must be merely sensitive nerves; and that in the event of disease producing paralysis of these nerves, the effect on the parts supplied by them ought to be loss of sensibility alone; and that, as these nerves cannot confer motive power, muscular action should not be disturbed by paralysis of them; and thus exactly we have it in the case before us. There is loss of sensibility in all the parts

of the face and interior of the mouth, supplied by those branches, but no loss of muscular power. Thus anatomy and physiology explain to us those symptoms which otherwise would be inexplicable, and again, pathology, more beautifully than a thousand experiments, confirms the accuracy of our anatomical observations, and the truth our physiology of this nerve.

Sensation, we have seen, is perfect along the lower jaw below a line drawn from the angle of the mouth towards the lobe of the ear. The parts below this line, the skin of the cheek, the chin, and the gum of the lower jaw, are supplied by the third branch of the fifth, namely, the inferior maxillary nerve. Now, does the preservation of sensibility in the lower part of the cheek, while it is lost in the upper part—or, in other words, does the continuance of function in the third branch of the sensitive root of the fifth, while it is lost in the first and second branch, lead to any practical result in diagnosis and prognosis? With the light of anatomy it does, and to a very important one. It tells us that the disease which has deprived the first and second branches of the fifth of their function of sensibility is not disease of the brain, nor, probably, has it its seat within the cavity of the skull; for if the diseased action attacked the nerve previously to its forming the Casserian ganglion from which all three branches take their origin, then it would be nearly impossible that the function of the third or inferior maxillary branch should not have been equally destroyed with the functions of the other two. Were the disease within the skull, it is also most probable that the motor root of the fifth, which in part of its course lies in very close relation to the sensitive root, should suffer equally. But as the motor trunk and the third branch of the sensitive trunk are not injured, we are justified in concluding that the cause of the paralysis of sensibility of the first and second branches has its seat external to the cavity of the skull, and the diagnosis thus made leads of course to the more favourable prognosis. Thus, anatomy and physiology here lead us both to diagnosis and prognosis. With this instance before you, to shew you the value of the observation, let me entreat of you never to lay aside anatomy or physiology in studying practical medicine. How different now is our interest in this case, and how superior our knowledge of it, when we have thus taught ourselves that even in disease the symptoms which present themselves are not the result of mere chance, but are in strict accordance with the laws of healthy action! If there were no other result from

this analysis of the symptoms of this case than the attractive investigation of some of the functions of the nervous system, and the conformation of our physiological knowledge, this alone should make us study the symptoms with enthusiastic interest; but when we find that on this analysis depends our knowledge of the nature of the disease, its study then becomes a duty. There is, I am sorry to say, a growing tendency to substitute what is called observation at the bed side for anatomical and physiological investigations of structure and symptoms. Such a doctrine is very acceptable to the ignorant empiric and the indolent student; but to expect to attain sound knowledge by such a course, would be as reasonable as it would be in a mechanist to expect that he could ever attain a knowledge of the derangements of a machine, without bringing to his assistance a knowledge of its structure and its powers.

If we now turn our attention to the inferior maxillary nerve, the third branch of the sixth, and to the portio dura of the seventh, we shall find in the physiology of these nerves an explanation of some curious forms of nervous affections of the face, and to which we find almost nothing analogous in any other part of the body.

The first is that in which the seventh or portio dura alone is paralyzed.

I saw a lady some time since, whose features were undisturbed and free from distortion when at rest, but when she laughed or smiled, the muscles on the right side alone acted, while the left side of the face remained perfectly passive, thus giving to the countenance the hideous expression of half of a living and of a dead face being joined together. In such a case as this the paralysis is confined to the seventh nerve, the motor branch of the fifth being unaffected. While the face is at rest, the motor branches of the fifth at each side neutralize each other, and there is no distortion; but on the seventh or portio dura being called into action as a nerve of expression, the nerve of one side alone acts, and thus this singular form of paralysis is produced.

In contrast with this may be placed a case of paralysis of the third branch of the fifth, the inferior maxillary nerve. The case is from Sir C. Bell's work on the Nervous System.

A man affected with hemiplegia was paralytic of the right side of the face, which was also insensible on being pricked with a needle.

When at rest, the right side of the mouth and the right cheek hung down, and the saliva constantly flowed from it. But when he was made to sneeze, to laugh, or to whistle, the distortion disappeared,

and both sides of the face acted equally. Thus these cases are contrasted with one another. In paralysis of the portio dura alone, *there is no paralysis when the muscles of the face are at rest*, but it becomes most disagreeably evident by distortion on giving expression to the face. *In paralysis of the third branch of the fifth there is paralysis of the face when at rest*; but when a respiratory expression calls the seventh into action, the paralysis for the time being disappears.

The most common form of paralysis of the face is when both the third branch of the fifth and the portio dura are simultaneously affected, so that there is paralysis both when the features of the face are at rest, and in the expression of laughing, sneezing, &c. Such is the following case:—

Michael Keefe, admitted into this hospital December 3. About ten days before, he felt his upper lip swelled, and next day perceived that, in attempting to masticate, he could not turn the morsel in the right side of his mouth. On admission his mouth was drawn to the left side; he was unable to close the eyelid of the right eye; he could not whistle, and when he laughed the left side of the face alone acted. In this case both the seventh and the third branch of the fifth of the right side were paralysed, for there was in the case a combination of the symptoms of the two former cases. There was inability to masticate, and there was distortion of the face when at rest, dependent on paralysis of the third branch of the fifth; and there was also distortion of the face in expression, indicating paralysis of the portio dura.

We have thus the following form of local paralysis of the face:—

1st. Paralysis of sensibility, as in the case now in hospital, the muscular power being unaffected—dependent on disease of first and second branch of the sensifc root of the fifth pair of nerves.

2d. Paralysis, not visible when the features are at rest, but most strongly marked when any respiratory expression, such as sneezing, laughing, &c. is attempted—dependent on disease of portio dura.

3d. Paralysis, persistent when the face is at rest, but temporarily suspended when any respiratory expression is attempted—dependent on disease of the third, or compound moto-sensifc branch of the fifth.

4th. Paralysis of the face both at rest and in motion, in which both the portio dura and third branch of the fifth are implicated.

For the experiments and some of the cases on which I have grounded these observations, I must refer you to Sir Charles Bell's work on the Nerves. There is, however, in some parts of that work an obscu-

rity, and occasionally an apparent contradiction, which may render its perusal difficult. You will obviate the difficulty by consulting Dr. O'Beirne's analytical correction of Sir Charles Bell's work. It is published as an appendix to Dr. O'Beirne's work on Defæcation, and it will well repay you for a perusal. To return to our case in hospital. I have already given my reasons, founded on the immunity of the inferior maxillary nerve, for thinking that in this case the disease is not within the cavity of the cranium, or at least between the Casserian ganglion and the origin of the nerve. It is probable that the injury which this patient received produced periostitis of a subacute or chronic form, and that this, creeping along the temporal surface of the sphenoid bone, has also spread through the spheno-maxillary fissure to the lining membrane of the orbit, and has then involved the first and second branches of the fifth. This view is strengthened by the circumstance of there being still a small space in the upper part of the temporal hollow which is painful under pressure. I shall therefore, for some time longer, continue the same line of treatment under which he at present is, viz. repeated local blood-letting and blistering, and the exhibition of a mild course of mercury. The head symptoms, the vertigo, &c. have ceased, the motion of the pupil has become natural, and the sight is much improved, so that we have to contend with only the local tenderness in the temple, and the loss of sensibility of the first and second branches of the fifth.

P.S.—Since the above was delivered, numbness, accompanied with loss of power, began to extend to the lower jaw, shewing that the diseased action was beginning to implicate the third, or compound branch of the fifth. The whole head was then rubbed over with antimonial mercurial ointment and iodine; the amendment was rapid, and she soon after left the hospital with scarcely a trace of the disease.

CLINICAL OBSERVATIONS ON FEVER.

BY CHARLES LENDRICK, M.D. T.C.D.

Queen's Professor of the Practice of Medicine in the School of Physic in Ireland.

FEVER was described in the synopsis of my course of lectures on the *Practice of Medicine*, published in the year 1833, as a disease dependent on "*morbid actions* NOT

referable to any particular structure or system." In thus denying the essential connexion of fever with organic lesions, or morbid changes of the fluids, I did not, nor do I now, claim originality. In my opinion, the priority as to time, in alleging a fact, is but a poor test of professional knowledge; and the palm ought to be assigned, not to him who (perhaps accidentally) stumbled on the truth in the first instance, but to those who, in opposition to fashionable theories and received doctrines, steadily upheld what proved to be established on the most solid grounds. In making this remark, I wish to be understood as referring to the expressed opinions of able and experienced practitioners in Dublin, who, for probably half a century, have, through evil report and good report, denied the hypotheses of both solidists and fluidists, as explaining the source of fever.

I am not an advocate for authority in medicine; yet I confess that when, many years ago, I considered the extensive opportunities that Dublin affords to the practitioner, in fever—the enormous prevalence of that disease in our metropolis—the excellence of its principal institution (in Cork Street) for the reception of fever patients—and the consummate skill and experience of such men as Quin, Purcell, Harvey, Plunkett, Perceval, &c., I felt, even at a very early period of my career as a medical man, an inclination to doubt the theories so imposingly put forward by authors whose opportunities were so much inferior to those of the distinguished practitioners I have just mentioned, and which, in my opinion, were the less deserving of confidence, from the overweening confidence with which they were urged.

On perusing, several years since, Travers's work on Constitutional Irritation, I was struck by the coincidence between his statements and my own experience. I asked myself the question repeatedly—"Did I not know all this before?" It seemed to me that I had learned nothing new, as is the case with most persons after they have become acquainted with the discoveries of others. Medical discovery, however, generally merely renders clear what was formerly obscure; and we are too apt to confound the twilight of our own recollections with the clear elucidation of the subject by others.

When I had methodized my thoughts, after a perusal of Travers's work, and its comparison with (or rather confirmation by) what I had observed, it seemed to me that there was no important distinction (contagion excepted) between fever and what he termed constitutional irritation. A fracture—a contusion—a wound—any injury, however slight, appeared to be capa-

ble of producing all the phenomena of fever. Delirium—coma—convulsions—a surface hot, cold, or flooded by perspiration—excessive and depraved secretions, or a stoppage of these secretions—every imaginable variation in the state of the human economy was capable of being produced by the most trifling irritation of the nervous system, under peculiar circumstances.

Here is an important point established in our analysis. A similarity of effect goes a certain way in proving a similarity of cause. The identity, however, of fever with constitutional irritation admits of further proof.

1st. In both diseases the influence of an external cause is requisite to produce the effect. In that of constitutional irritation, the impression of a local irritant on the nervous system is obvious, from the effect of the external injury. In the case of fever, the nature of the influence of a cause external to the system is much more obscure; but the necessity of such a cause in order to produce the usual effect is undeniable. What are called the "accessory" causes of fever—cold, mental anxiety, intemperance, &c. are quite inadequate in themselves to its production; they may establish an inflammatory or nervous disease, but they will not cause typhus fever, unless typhus be prevalent in the district at the time, or unless the patient has been exposed to contagion. Then, the means which on other occasions produce other diseases will engender typhus fever of the worst description. In contagion, and what are called epidemic and endemic agency, whether combined or uncombined with the accessory causes of fever, we therefore have a principle, which in this disease is equivalent to the influence of an external injury in producing constitutional irritation.

2dly. In both fever and constitutional irritation, we observe the same influence of the constitutional powers of the individual affected. While all the symptoms of this morbid state are produced by an external injury, a similar, or a much greater injury, will be borne by another patient with not the tenth part of the constitutional disturbance. So in the case of fever, several persons will be similarly situated as to the influence of pestilential agency or contagion; yet one will be attacked by typhus fever of intense severity, another will labour under merely a *febricula*, while a third will escape altogether.

3dly. Organic changes take place in both diseases under similar circumstances. If the patient be predisposed to any organic affection, it is sure to display itself during the perturbation of the system consequent on the establishment of fever or constitutional irritation. This will hap-

pen even at an early period, and to a considerable amount, if the patient has been much exposed to the operation of those agents, cold, vicissitudes, &c., which are accessory in the production of the febrile affection, and which exert the principal influence in forming organic disease.

Constitutional irritation thus renders us powerful pathological assistance, by shewing the capability of an external and remote irritation of the nervous system to produce *organic disease*, as well as a constitutional disturbance similar to fever. A man receives a bruise on his head; severe constitutional disturbance supervenes; he displays symptoms of local disease in the thoracic or abdominal viscera; he dies, and the expected organic changes are discovered. Here no one can say that pneumonia or hepatitis was the *cause* of the disease, which is distinctly referrible to an obvious injury inflicted on a limb. Hence we arrive at the conclusion, that the *occasional* appearance of certain organic changes in *fever* ought not to induce us to refer the cause of this disease to them. We cannot trace out its exciting cause, contagion, &c., with such facility as in the case of external injury; but the circumstance that there is an external cause in operation (although more obscurely), and with nearly similar results, in the one case as in the other, and that in both there are the same variations as to the occurrence of organic affections, whether as to this taking place at all, or in any particular form, afford confirmation to the great similarity (or nearly identity) of fever and constitutional irritation. Now as the latter is clearly referrible to an external impression made on the nervous system, modified by the constitutional idiosyncrasy of the individual, and by the operation of what are termed accessory causes, ought not FEVER to be referred to a similar source—with the substitution of contagion, or epidemic, or endemic agency, for injury, &c.?

Some say, "Any pathology rather than none." This I deny. The person who knows by experience merely that a certain remedy applied in a certain way will cure a disease, and who proceeds on this principle, is a far safer practitioner than he who adopts erroneous opinions, and *acts* on them. The reason that false pathology has not done so much mischief as might have been expected is, that practitioners often theorise about disease in one way, and practise in another. Their theory is unfounded, but their practice, based on their experience, and not on their avowed principles, is correct.

Among the many physicians who have been distinguished in Dublin for their skill in the treatment of fever, none perhaps have attained to so great a celebrity as the

late Dr. Harvey, nor has there appeared since any one so conspicuous for the successful management of what seemed to be desperate cases. I endeavoured, at an early period of my professional career, to make myself acquainted with his rules of practice; and the most accurate information I could acquire was, that his great secret consisted in doing "*very little*." It was a sarcastic remark of his, that "the patient was in greater danger from the doctor, than from the disease."

It is not unlikely that a modification of this remark of Dr. Harvey is applicable to many diseases besides fever. It is still in reserve for us to learn, how disease will subside without the daily administration of medicine, or how far it is a provision of nature that it shall run its course, and then terminate favourably. For instance, a principle most confidently inculcated formerly, that the tendency of cholera is always to a fatal termination, and that the patient is never saved but by art, was disproved by the fact frequently observed in Ireland, that paupers left in the last stage of cholera asphyxia to die in a ditch, recovered notwithstanding, and without the use of any medicine but cold water.

"What is to be *done*," is a frequent question at medical consultations. It is often, however, of more consequence to know what is *not* to be done; and the practitioner often cannot display greater skill in fever than by knowing when to do nothing. By adopting the negative mode of treatment in the great proportion of cases, and by interfering in the others only to the amount actually indispensable, during my attendance at Sir Patrick Dun's Hospital, when fever was unusually prevalent two years ago, I lost but two patients; one of whom was a confirmed drunkard, and the other laboured under long-established emphysema of the lungs, complicated with bronchitis. For the latter disease, rather than fever, she was admitted into the hospital.

It is fully established, that patients will recover in a great majority of instances from typhus fever, by the almost unassisted powers of nature. In many such cases, especially among the lower orders of society, such is the torpor of the functions, partly from the disease, and partly from previous habits, that a medical attendant can scarcely do harm by any practice confined within reasonable bounds; and whether he bleeds and purges on the one hand, or uses bark and wine on the other, provided he does so moderately, he will not *prevent* the patient's recovery. This fact has not only led to the undeserved reputation of alleged specific modes of treatment in fever, by a coincidence of spontaneous recovery with

their supposed effects, but has also caused an opprobrium to our profession, namely, that statistical returns prove that the average amount of mortality is nearly the same under one mode of treatment as another. The reason of this, however, is, that the *average* mortality is influenced by the *large* proportion of cases, which are of the description I have mentioned, where almost any treatment or no treatment is equally successful as to the result. It is in the *small* proportion that medical skill and the effects of medical treatment are shewn; and these, from their fewness, but little affect statistical returns. In such cases the practitioner is constantly between Scylla and Charybdis; and whether the necessities of the case require bleeding, purging, mercury, wine, or other stimulants, whatever is done beyond what is actually *necessary*, is done injuriously.

Typhus fever presents itself in two forms; typhus, properly so called, and the synchus of Cullen, where local inflammation to a greater or lesser extent is combined with typhus. The distinction of such cases, and the mode of treatment, will be referred to hereafter; for the present, I cannot too strongly urge the danger of being led astray by that perturbation of the system which once led to the hypothesis of a fermentation of the fluids; and under the operation of which, local disease, which in itself might require active and special treatment, is liable to be simulated. Thus, with disturbance of local functions, or determination of blood to various parts, unusual secretions take place in the respiratory organs, as elsewhere; and which, on the application of auscultation, seem to depend on organic disease. I have been repeatedly assured by others, after the application of the stethoscope, that the lungs were softening, or that latent pneumonia was present; and yet the physical signs subsided, without any direct treatment, on convalescence from fever being established.

I particularly distrust *crepitus*, when existing merely in the *gravitating* portion of the lung. I have repeatedly observed it at the back of the thorax, when I am convinced, from the progress of the case, that it depended merely on a general secretion which had become accumulated there in consequence of the supine posture of the patient. I therefore rarely direct any special treatment for mere crepitus, when occurring in typhus fever; inasmuch as there is less danger in allowing pneumonia, if present, to further develop itself, than to venture on bleeding, mercurialization, or the action of tartarized antimony, *unnecessarily*, in typhus. Admitting, as I do, the value of stethoscopy, I am sorry to say that its applica-

tion in *typhus fever* has, in my opinion, destroyed more lives by the effects of contagion, among medical practitioners and pupils, than it has saved among their patients, by the information it afforded available for practical purposes. Among the former, I may mention the instance of my lamented friend, Dr. Stack, formerly professor in the School of Physic, and physician to Sir Patrick Dun's Hospital, who, unfortunately for himself, had become imbued with the notion, either that fever was but little contagious or that he was proof against its influence; and although his long exposure with impunity, while stethoscoping fever patients, seemed almost to countenance such a supposition, his premature death, undoubtedly, and with his own assent, referable to contagion, afforded a link in the chain of proof as to the danger of the practice, since fully made up by numerous and lamentable instances.

I wish it to be understood that *clinical* lectures are to be considered as commentaries on disease rather than its description; and that even where the individual cases under hospital treatment are not referred to. I mention this in explanation of the cause of frequent omissions with respect to symptoms and treatment, and which, as well as homeliness of expression, might be avoided in a more methodical consideration of the subject.

[To be continued.]

REMARKS ON THE OFFICE OF CORONER.

REPLY TO MR. CHATTO.

To the Editor of the Medical Gazette.

SIR,

IN your last number a paper by Mr. Chatto—"Objections to a Medical Coroner"—attracted my attention; and in consequence you are troubled with the present communication, which, should you deem it worthy of a place in your column, you will oblige me by inserting in your journal at your convenience.

In many of Mr. Chatto's remarks I admit that there is a great degree of plausibility, and, if the appointment were vested in the hands of well-educated barristers, I would even say truth. But, sir, if we calmly look around us, and consider the qualifications of those who fill such appointments, it will, I think, be admitted that any medical man (however *mediocre*),

of modern education, must be quite as competent as any attorney, not possessed of extraordinary medico-legal knowledge, can be to discharge the duties of this very important office. This will be more apparent when we recollect that the functions of coroner are now restricted to the investigation of the causes of death, and the concomitant circumstances. Had even the old regime existed, it appears to me that a medical man and an *appraiser* should have conjointly filled the office. In consequence of the existing law so restricting the duties of the coroner, I must be allowed to express my entire dissent from the opinions entertained by Mr. Chatto; and but for the invidious nature of such a task, it would not be difficult to convince Mr. Chatto himself of the justice of what is now advanced. As to the appointment of a medical officer, "handsomely paid," one of whose principal duties should consist in examining the bodies of those found dead under unusual circumstances, I ask Mr. Chatto, and your readers generally, what possible benefit could arise from the existence of such a functionary, unless he were subject to examination by a man at once competent to duly appreciate the value of his report, and to comprehend the validity or fallacy of its statements? This principle of medical appointments is subject to other objections: at present I shall mention but one, viz.:—A medical man of very ordinary attainments may attend a case demanding after death an inquiry. In the ordinary course of events the man who attended the deceased should be an important witness; but, according to Mr. C.'s scheme, his place is to be usurped by the well-paid functionary, whose only knowledge is to arise from a *post-mortem* examination. Were such a plan adopted, my humble opinion is, "the decisions would (in all probability) then become (not) consistent (*but inconsistent*) with common sense and actual facts." Such cases have fallen under my own observation, both when I served as coroner and subsequent to that period. I will even go a little further than this, and declare it as my honest opinion, that unless the office be filled by a man well acquainted with forensic medicine, the inquest becomes neither more nor less than a solemn mockery, and in some instances a very melancholy one. A verdict was, for example, returned on the

body of a friend of my own, of "*felo de se*," where I could have proved *more* than eccentricity; and but for the fact that the inquest was conducted by a coroner surpassed by his jury alone in ignorance, the verdict must have been "insanity." Now, sir, there is another point in Mr. Chatto's letter which demands comment—viz., the duty of the coroner.

I admit that in the literal sense a coroner is not called upon to "direct" the jury; but, sir, it is his most important duty to elicit the truth, and to *criticise* the evidence, and to assist the jury to the utmost of his power. If such be not the case, why saddle the country with a useless expense? Why not simply entrust such an inquiry to a jury, which, like the grand jury, might elect a chairman from amongst its members? By such a course two expensive offices would be abolished, if Mr. Chatto's views are founded on correct premises. An objection (not adverted to by Mr. Chatto) exists in the mind of the public as to medical coroners—viz., "that medical men are not qualified to obtain evidence." Now, sir, if we reflect upon the nature of medical science, its niceties, and almost imperceptible distinctions, especially as regards diagnosis, it appears to me that, with the exception of the barrister, no man can or should be better qualified than a medical man. I agree with Mr. Chatto, that Mr. Wakley's observations were quite strong enough on the occasion alluded to; and having conducted an inquiry into a case of drowning supposed to be connected with murder, I do not express this opinion unadvisedly.

Having devoted a considerable portion of that time not occupied by the practical duties of my profession to legal medicine, I hope that these observations will not be deemed altogether gratuitous.—I am, sir,

Your obedient servant,

GEORGE FIFE, M.D.

Newcastle-upon-Tyne, March 20th, 1839.

ON THE EAR.

NO. I.

To the Editor of the Medical Gazette.

SIR,

DR. DELEAU, Jun. published last year, at Paris, a work of about 425 pages,

on the Catheterism of the Eustachian Tube, and the employment of Atmospheric Air in the Maladies of the Middle Ear.

To this work I have had my attention directed by a friend, and I beg to offer a few remarks upon it, including, as I proceed, extracts of some curious portions.

Dr. Deleau's plan appears to be the introduction of a flexible gum elastic tube, containing what he calls a mandrel of soft silver wire, whereby the curve of the tube can be preserved, and the flexible tube be inserted into the Eustachian tube (the guttural conduit leading to the cavity of the tympanum) by passing it through the nose. The wire is next withdrawn, the tube is attached to the cartilage of the nostril by little silver nippers, and the outer extremity of this flexible catheter is then united with a larger flexible tube, connected with a vessel of a bell-like shape, containing condensed air, which, by turning a stop-cock, is injected into the Eustachian tube in douches or jets. This method of operation I gather, not only from the work itself, but also from the report made to me by a gentleman who went to Paris to consult Dr. Deleau, and was operated upon in this manner, without, however, deriving any benefit.

Dr. Deleau gives the Report of the Royal Academy of Sciences at Paris, wherein is assigned to Guyot, post-master at Versailles, the credit due to the idea of passing a tube and injecting warm water into the Eustachian tube, to cleanse the cavity of the tympanum from any obstruction that might exist there. Guyot is described, in this report, as being well acquainted with the organization of the ear and with the mechanism of hearing, and that he introduced a hollow probe into the entrance of the Eustachian tube, and injected warm water, which removed the impacted mucus, and gave him the faculty of hearing. Guyot has before been brought forward upon several occasions, and one person absolutely advertised that the operation, as invented by the Sieur Guyot, was performed by him. Now had the persons who drew up the report above quoted, taken the trouble to refer back to about 1726, they would have discovered that the subject then underwent a very serious and close examination before the members of this

very Academy. Guyot was also examined; and the result of their deliberations was, that Guyot had never reached the Eustachian tube by the way he had imagined he had accomplished it, namely, through the mouth, which the members of the Academy decided was impracticable even in the dead subject, and much more so in the living. That Guyot was benefited in some degree in his sense of hearing appears to be admitted; but, independent of this solemn decision of the Royal Academy, it will surely not be pretended by any competent anatomist at the present day, that a tube, or any instrument, can be passed through the mouth upwards behind the tonsils, and then laterally into the Eustachian tube. I have always considered whatever improvement Guyot gained in the sense of hearing was through his injecting the warm water into the pharynx through the mouth, which produced a species of suffocating sensation, and tendency to vomit, and that these efforts caused the Eustachian tubes to throw out the mucus with which they were obstructed; but I am of opinion that a gargle, used when the body is in a horizontal position, will produce quite as good an effect, if not better, than any injection into the Eustachian tube, even accomplished by the more reasonable passage through the nose. Mr. Cleland attempted the performance of the operation through the mouth, but failed. Mr. Douglas demonstrated, upon the dead subject, the possibility of passing a bent probe through the nose into the Eustachian tube. Mr. Wathen, about 1755, introduced a bent silver tube through the nose into the Eustachian passage, and connecting the end with a syringe injected warm water therein; but his success in the few cases upon which he experimented were not, it is believed, such as to tempt him to proceed further. The Academy, however, in their recent report, not only omit all account of the former decisions upon Guyot's experiment, but accuse our countrymen, Douglas and Wathen, of following the same method, ascribing most unjustly to Desault, a French surgeon, the discovery of passing the tube through the nose. In this country we find no account of any surgeon having attempted this operation until 1818, when I tried it in several instances; but I do not think that it is superior to a gargle if

properly used. In France, M. Boyer, M. Itard, and Dr. Saisay, were the persons who adopted this method; but we heard little of the effects produced.

I will now revert to a consideration of Dr. Deleau's plan of sending in jets of air. I will grant that he inserts his elastic tube into the Eustachian conduit, which is filled with mucus, as well as the *cavitas tympani*, and that in withdrawing the silver wire which serves to give it the proper curve, the tube is not withdrawn out of the situation in which it had been placed—a matter, however, very problematical—the jet of air rushes into the passage already closed by the elastic tube, impacting and condensing the whole into a more solid mass, if before of a caseous consistency, but if in a more fluid state driving it into the mastoid cells, where it very probably will occasion serious mischiefs, such as I will endeavour to describe in a continuation of this subject.—I am, sir,

Your obedient servant,

W. WRIGHT,
Surgeon-Aurist.

13, Salisbury Square, Fleet Street.
March 18, 1839.

MR. M'LELLAN'S CASE OF STRANGULATED HERNIA.

To the Editor of the Medical Gazette.

SIR,

WHEN a practitioner records instances of disease in some rare forms—when he proves the peculiar value of some remedial measure—when he confirms the propriety of some rule of practice—or when, by pointing out the sources of his own mistakes in diagnosis or treatment, he succeeds in erecting himself as a beacon, and by that means enables others to avoid the errors which have been injurious to him, he does a service to the science of medicine; but he who, in the face of facts, plausibly endeavours to make the ultimate termination of a case correspond with his own diagnosis at the commencement, and, more ingeniously than justly, dovetails the symptoms as they occur, with some acknowledged description of a particular form of disease, only renders more obscure what it should be his object to set in as clear a light as possible.

I read with interest a case recorded

in the *MEDICAL GAZETTE* of March 2d, but, from the heading, I should have expected rather more undeniable proofs of the fact assumed—viz. that recovery took place in a case of strangulated hernia, after the symptoms had existed for fourteen days. These symptoms, as recorded by Mr. M'LeLLan, were as follows:—

“It (the tumor) was slightly *elastic*, having the feel of *intestine* rather than *omentum*, and only admitted of partial diminution on continued pressure. There was considerable anxiety and restlessness; sense of painful constriction across the abdomen; nausea and vomiting of the fluids she drank, mixed with bile, and afterwards with feces. *Constipation of several days' duration*; skin covered with a clammy perspiration; tongue furred and dry; thirst urgent; pulse sharp and accelerated, and respiration oppressed. *There was hardly any pain at the neck of the tumor, and no tenderness of abdomen.* The taxis failing to produce any permanent effect, a consultation agreed on the propriety of an immediate operation.”

In addition to this, we are informed that the woman had been the subject of an *irreducible* hernia for 50 years, and that nothing would induce the patient to submit to an operation, for even she could not understand the connexion between the old hernia and her present sufferings; in short, says the writer, she determined rather “to die than be cut.” The stercoraceous vomiting increases daily until on the eighth day, when a marked remission occurs; the patient asks for food, and expresses herself better; gangrene of the intestine is now suspected. About the fourteenth day after, continuing to eat and improve, she passes two copious stools, and by the aid of warm water enemata, “upwards of a dozen” more, “ten days after all remedial means had been abandoned.”

Mr. M'LeLLan, by a strange perversion of reasoning on the case, says (even after its favourable termination), “It was doubtless a strangulated hernia, resisting all means short of operation.” We are, however, kept quite in the dark as to the means which had been adopted previously to the abandonment of the *vis medicatrix naturæ*.

May I be excused if I insinuate that

a much more common-place view might be taken of the case; such a one as to make it serve as a caution to young practitioners to give nature every seasonable chance of assisting herself, without the dubious benefit of their interference?

Is there, I would ask, in the history of symptoms, as related by Mr. McLellan, any thing very contradictory to the following view of the matter?—that the symptoms depended wholly upon fecal accumulation in the intestines, independent of the old hernia, which is distinctly stated to feel as containing “*intestine*, rather than *omentum*.” This accumulation (fourteen copious evacuations) was surely sufficient to account for the constriction across the abdomen, the vomiting, the oppressed respiration, and febrile symptoms; while the absence of pain or tenderness in the tumor or abdomen, as also of hicough, serve negatively to confirm this view of the subject. From neglect of the bowels, they had become inordinately distended, and thus such a degree of torpidity was induced as to prevent the accumulation from making its exit in the usual manner: nature, however, endeavoured to relieve this state of affairs by inducing the vomiting; the system relieved thus far, the accumulation was diminished sufficiently to allow the intestine to resume its functions, and, by consequence, all the symptoms vanished. Had the old woman submitted to the operation when she was advised, what would have been the benefit? I opine the case would then have been complete in its kind, and would have served to place in juxtaposition with instances of dry tapping, ill calculated operations for stone, or any similar practical *faux pas*.—I am, sir,

Your obedient servant,

H. G. HARBORD.

Liverpool, March 21, 1839.

THE PREVALENT EPIDEMIC.

To the Editor of the Medical Gazette.

SIR,

WITH your permission I will take the liberty of drawing the attention of your readers to the principal symptoms of an epidemic now prevailing in this metropolis.

The first signs of an attack are pains at the epigastrium and hypochondria, generally increased by pressure, giving rise in some instances to the suspicion of inflammation. There is anorexia, much lassitude, an excited pulse, a white tongue, and a hot skin. In a few hours a well-marked shivering attack is observed, succeeded by fever of a remitting character; during which the strength is completely prostrated, and the mental powers considerably disturbed. The pulse rises to 120, but is very feeble; the heat of surface is extreme, the pains of the side severe, and the sleep much disturbed. After continuing three or four days, the symptoms begin to subside, generally terminating with profuse perspiration.

But the most remarkable feature in this epidemic remains to be noticed. Although the illness has not continued more than three or four days, such has been the shock upon the nervous system that it leaves the patient completely prostrated. His countenance expresses much debility; the voice becomes feeble; and when he attempts to walk, he is seized with instant vertigo, and obliged to desist. Days and weeks elapse before the strength is restored; and where the patients are of delicate habits, and advanced in life, there is danger of their sinking under the shock that they have sustained.

The principal point to be observed in the treatment of this disorder is to avoid the use of the lancet. Cases have come under my notice where blood-letting has been employed to combat supposed inflammation, in which the consequences have been most deplorable. In fact, little treatment is necessary, except keeping the bowels open, and the exhibition of saline aperients. In some cases, however, it is necessary to prescribe diffusible stimulants, or tonic remedies, even from the commencement of the attack.

These remarks may be sufficient to draw the attention of your correspondents to this important subject, by which means communications of greater importance may be elicited.

I remain, sir,

Your obedient servant,

LONDINENSIS.

"Licet omnibus, licet etiam mihi, dignitatem
Artis Medicæ tueri; potestas modo veniendi in
 publicum sit, dicendi periculum non recuso."

CICERO.

QUACK MEDICINES.

A CURIOUS topic, not touched upon by Dr. Cowan, nor, as far as we know, by any other writer on quackery, is the immense multiplication of trifling diseases which attends on the advancement of civilization; so that, great as is the increase of the medical army, still greater is that of the foes whom they have to subdue. It is true, that in large towns the constant though still half-stifled complaint of our host is, that they have no practice; but this is to be understood of the lack of those who help to pay the baker's bill; the simple patient is not very difficult to procure. The reasons of this enormous overflow we apprehend to be chiefly two: the first is, that in ruder ages a smaller proportion of those weakly children is reared, to whom life is a long disease; and, secondly, that among the boors of an unrefined community, either small ailments are of less frequent occurrence, or, when they occur, are allowed to take their course almost unnoticed. Slight catarrhs, headaches, and chronic eruptions, induce millions at the present time to seek for medical advice in some shape, who would formerly have been scarcely conscious of the disorder, as we still see among labourers of the lowest class. But the capability of paying for regular advice can hardly be supposed to have kept pace with the rapid progress of social refinement; and many persons spend a large portion of their time in an uneasy criticism of their own sensations, who are incapable of remunerating a medical practitioner of the most moderate pretensions. This, if we mistake not,

is a reason, and a weighty one, why in London and other great towns, where there is an apparent superfluity of regular practitioners, irregular aids of every kind should likewise abound. Advertised and unadvertised nostrums, family receipts, amateur attempts, conjectures of literary men, prescriptions spelled out of Buchan's Domestic Medicine, and doctorings by tailors and weavers at 2s. 6d. a case, are merely a few examples of the way in which the insatiable thirst for health is slaked at very muddy fountains. To endeavour to put all this down by informers and policemen would be intolerable; it would be like flogging a negro for eating dirt, instead of giving him the absorbent which is required to quell the cravings of his maulady. In one of those stringent clauses which we quoted in our last number, Dr. Cowan proposes to punish every one who even attempts to practise without a legal qualification, but excepts the gratuitous administration of remedies when medical advice cannot be procured. But what if it can be procured, only rather far-fetched and dear-bought, and, unfortunately, not commanding the confidence of the sick man, while Buchan, with a friendly interpreter and a medicine chest, are on the spot? The answer is clear enough: the clause is peremptory, and the amateur prescriber (suppose the clergyman of the parish) must pay his fine, and perhaps go to gaol to boot. We shrewdly suspect that such an event would not tend to make the faculty very popular in the district; especially if the case had prospered. But Dr. Cowan will say, take a case of a contrary kind, and see what you can make of that. The other day, for instance, as we read in the newspapers, a girl in the country drank a decoction of yew-leaves, for worms, and died in consequence. If the adviser had been fined or imprisoned for a short time, it might have tended to

check the destructive zeal of lay practitioners. True; but this could have been done without any new law, as the prescriber might have been put on his trial for manslaughter. Even in such cases, however, the public feeling is rarely strong against the misdoer: when it is proposed to protect the simple against this species of wrong, they cry out that they do not want to be protected; like the wife of the wood-cutter in Moliere, who is angry with the relation that endeavours to save her from being beaten by her husband, and exclaims, "*Je veux qu'il me batte.*"

We would mention that Dr. Barlow, one of the authorities quoted by our author, settles the question of lay-practice very succinctly, and says, that "to attempt to restrain the public from seeking advice in any quarter, or any individual from giving it when applied to, is absurd, and must ever prove nugatory; for the public never will submit to such dictation." Of course this toleration does not extend to passing over cases like that of the yew-leaves, but manslaughterers with drugs must take their chance at the Old Bailey, like those who kill with knife or pistol.

The public, again—and it is by them, and not by a medical tribunal, that the whole question is to be decided—will not pity us much when we talk, as Dr. Cowan does, of the long and expensive education of medical men. In the first place, the sect of Pyrrhonists will doubt whether, in many cases, the education was either long or costly; and secondly, the sterner critics require that the fruits of this education shall be shewn, not in parchment diplomas, nor accounts of monies expended, but in sound practical knowledge, as well as general information. Without these, the finest rustling parchments are as inane as the crackling thorns upon the fire; with the difference, however, that they do not make the pot boil!

One of the arguments of the Fleet Street pamphleteers touches this point, and is ingenious enough. They ask, "How is it that medical men speak of their privileges being invaded, and their emoluments curtailed, by the sale of patent medicines, whilst they profess to consider those medicines not only useless, but injurious? Allowing them to be useless, they must be considered as benefiting members of the profession, by permitting the diseases of those resorting to them to gain ground; and thus rendering a longer and more lucrative attendance of the medical practitioner necessary. Allowing them to be injurious, the same argument holds good—in most cases in a stronger degree; because, not only does the disease for which relief is sought gain strength, but (except in those cases where death ensues, as a consequence of the application of the supposed remedy) the patient may possibly become a confirmed invalid, and afford a rich harvest to medical men for a long period of years."

Many a true word, says the proverb, is spoken in jest; and though Sharp, West, and Co. merely intend to be infinitely waggish, what they suppose must constantly happen. Whether the patient is driven to the nostrum by lack of cash to get advice, or by sheer despair, the dolorous cry, "That's so much out of our pockets!" seems misplaced in a professional mouth; and as for trying to protect the public by force against their own follies, we must repeat that we shall get as much credit as the kind relation in Moliere, while they shout out with all their lungs, "We like to be beaten."

As for persuasion, that is quite a different thing; we shall never cease to urge the diffusion of information. Teach the world that yew-leaves are dangerous, and safer vermifuges will be used; shew that colocynth cannot be

taken *ad libitum*, and the most notorious of pills will lose their popularity.

The men of Fleet Street conclude their pamphlet with a letter from a gentleman who has nothing to do with the sale of nostrums, but is deeply and passionately enamoured of them. "I am not the rose," says a Persian poet, "but I have lived near the rose." If the zealous correspondent is not a vender of infallible preparations, he must assuredly have been nursed in a patent medicine warehouse. Dalby's Carminative must have been imbibed with his mother's milk, and the Balm of Gilead must have soothed his maturer years, while he prudently reserved Morison's pills for the termination of his existence! Love is blind, and the unknown gentleman does not see the immense advantage that a prescription by the commonest apprentice has over a patent medicine; the apprentice sees his case, while the nostrum is a random hit. A probe thrust in the dark may be as fatal as a dagger.

In attempting to answer Dr. Cowan's argument that patent medicines ought to be put down by law equally with uncertificated practitioners, it appears to us that he does not state the case correctly. He supposes that the uncertificated practitioner cheats the public by pretending that he is licensed; while the vendor of nostrums has no such false pretence, but thrives by a continual chain of recommendations. We believe that the unlicensed practitioner rarely professes to be licensed, and that the public care very little about the matter, but go to him on the representations of those who believe themselves to have been benefited by his treatment, his original patients having been his private friends. Dr. Cowan's mistake appears to be in supposing, because the Apothecaries' Act is submitted to with but little murmuring, that the public would tolerate a law so stringent as to leave no loop-

hole to despair, poverty, or caprice. At present the iron hand of the law falls only on those who practise as apothecaries, while, if we may trust Gray, "the midwives, herbalists, cuppers, barbers, electricians, galvanisers, densists, farriers, veterinary surgeons, village wisemen, and cow-leeches, are left in full possession of their ancient practice, and may be employed by those who place confidence in them, as they cannot be confounded with apothecaries, though the chemist and druggist may*."

We have some doubts as to the quantum of practice which is left to these sages, as it is clear that to send in a bill for medicines, their advice having been previously given, would bring them under the Act. We must now conclude this subject for the present.

It is with reluctance that we have differed from so warm a friend of the profession as Dr. Cowan; but our conviction of the impracticability of most of his propositions has obliged us to do so; nor do we think it a compliment to a liberal profession to put down its rivals by force.

To diminish quackery, three things are specially required:—

1st. The improvement of our art. This will lessen the number of those who take nostrums from despair. It is by advancing the art which he practises, that every one must strive to show that his long and expensive education has bestowed upon him a privilege which the legislature need not guard by penalties—the privilege of discernment.

2ndly. The diffusion of knowledge on medical points, with particular reference to the danger of many drugs, and the absurdity of using any at random, by drawing them from the wheel of chance at a patent medicine shop.

* Supplement to the Pharmacopœia, 4th edit., p. xxvii.

This will diminish the number of those who fall into the clutches of the charlatan from ignorance or caprice.

3rdly. It is necessary to make good advice accessible to every one. Clubs or societies for the insurance of health must be formed on easy terms; and this will withdraw thousands who now fall a sacrifice through poverty.

CLINICAL LECTURES
ON
SURGERY,

Delivered at the Middlesex Hospital,

By MR. ARNOTT.

1. *Foreign Bodies under the Upper Eyelid.*
2. *Deep-seated yellow Opacity in the Eye, not dependent on Medullary Fungus.*
3. *Penetrating Ulcer of the Cornea.—Hernia Cornea.*
4. *Blepharospasmus.*

AFTER some remarks on the principal points to be attended to in the examination of diseased eyes, with a view to diagnosis, Mr. Arnott observed, that of injuries to this organ the most common are those produced by the access of foreign bodies to it. Most of these act mechanically; some, by their continued presence, causing irritation and inflammation; others, according to their form or the impulse given to them, producing a wound followed by the same results, or destroying the eye at once as an organ of vision.

A small particle of any substance getting into the eye, as is said, instead of being washed away by the copious flow of tears which immediately ensues, or being got rid of by the almost involuntary efforts of the patient for its removal, sometimes remains; and it is important to know where and how to look for it.

In examining an eye in which a foreign body is alleged to be, you first run over that part of the organ naturally exposed; look at the edge of the lids, to ascertain that it is not resting there—to the internal angle, where it is sometimes entangled—to the cornea, where sharp bodies are frequently imbedded—and to the exposed part of the conjunctiva. Not finding it, gently pull down and evert the lower lid, so as to expose its inner surface, and cause the patient at the same time to direct the globe upwards, so as to bring into view the whole of that gutter formed by the reflection of the conjunctiva from the lower lid to the globe. Failing to discover the foreign body here, you then evert the upper

lid; and this is easiest effected by taking hold of the ciliae with the finger and thumb of the left hand, and having placed a probe on the outer surface of the lid, just behind the posterior edge of the tarsal cartilage, you turn the lid over on the probe, so as to evert and expose its inner surface.

The inner surface of the upper lid is a very common seat of foreign bodies. A man of the name of Carne was admitted, on the 26th of Feb., into Hertford ward, with iritis, the symptoms of which, under the ordinary treatment, soon subsided. Some days after the redness had disappeared, it was observed to have recurred; but this was now seated exclusively in the conjunctiva, and the patient was questioned as to the cause, whether he had been out, &c. &c. He denied having been out, adding, however, that for a day or two he had felt as if something was in the eye. There was nothing observable in the exposed part of the organ, nor on the inner surface of the lower lid; but on everting the upper, there was perceived adhering to its concave surface a minute black particle of matter, which required the application of the edge of the flat end of the probe to effect its displacement. The sensation of which the man complained was now gone, and the redness of the eye soon disappeared.

About a fortnight ago a surgeon in the army came to my house, complaining of great pain in the eye, which was red, watering, and which he could not open voluntarily, arising from something having got into it two days previously. He had tried to remove it, and having had the pipe of a small syringe placed under the upper lid (to which situation he referred it), a stream of water had been thrown under the lid, in expectation of dislodging it, but ineffectually. On everting the lid, there was seated a small black speck on its inner surface, which being removed, the pain ceased, and the other symptoms followed.

A minute particle thus placed may remain for some time, so as to escape detection. Last September a lady felt something get into her eye as she was walking in the street. Her surgeon on repeated examinations could discover nothing; and as, notwithstanding the use of lotions, &c., the sensation still continued, and the eye was red and weak, at the end of eight days I was requested to see her. On everting the upper lid there stuck on its concave surface a small black speck, which being displaced, its effects quickly ceased.

If it is not discovered in the situation we have been just alluding to, and the sensation of it is still present, then it may be entangled in that part of the conjunc-

tiva which is reflected from the upper lid to the globe, and as this gutter cannot be brought into view, we sweep it by means of a camel's-hair pencil dipped in oil, passing this under the lid to its whole depth, from the inner to the outer angle of the eye.

For removing substances partially imbedded in the inner surface of the upper lid, or in the cornea, the instrument I shew you is useful; it is merely a thin piece of silver, the size of a cataract needle, but flattened like a minute scapula, having neither a sharp point or cutting edge, the edge being sufficiently thin to catch the projecting but partially imbedded foreign body, and yet not to wound the conjunctiva or cornea.

The substances impacted in the cornea are usually of metal, but any thing equally sharp will penetrate. A tradesman in Bond Street brought me his son, who, two days before, felt something get into his eye, where it still remained. I detected it in the cornea, removed it with this instrument, and receiving it on the nail, it appeared to me to be a bit of black sealing wax, which the lad confirmed, by stating that he was breaking a stick of it at the time he first experienced the sensation.

In connexion with the effects of injuries of the eye, the case of John Body, who was admitted on the 5th of December, presented some very interesting appearances. This lad had an affection of the left eye, the conjunctiva and sclerotica of which were red; the cornea, anterior chamber, and pupil clear, the latter of its ordinary size; the iris of its natural colour, but uninfluenced by the action of light, *i. e.* motionless. But the peculiarity of the case consisted in the existence at the bottom of the eye deep behind the plane of the lens (probably posterior to the vitreous humour), of a yellow substance, over the surface of which a number of the most delicate red vessels could be seen running, and pre-enting a very beautiful appearance. The vision of the eye was wholly lost.

Here were symptoms exactly corresponding to those presented by medullary sarcoma of the eye in its early stage; and most persons witnessing them for the first time, and ignorant of the history of the case, would have attributed them to that dreadful, and in the eye utterly hopeless disorder. But though Body was admitted on the 5th of December, this was a re-admission. He had originally come into the hospital three months and a half previously, *viz.* on the 21st of August, and under the following circumstances:—

A week previously a stick had been thrust into his left eye, and the sight im-

mediately destroyed. The conjunctiva and sclerotica were now crowded with red vessels, with chemosis of the former membrane. The cornea was transparent, but a bluish turbidity filled the anterior chamber, so as considerably to obscure the pupil and iris. The former, however, appeared to be of its natural size, but the condition of the latter could not be satisfactorily made out. At the outer part of the globe there was a wound of the sclerotica just at its juncture with the cornea, which was also in a very trifling degree involved.

With this condition of parts, and total loss of vision, there could be no question as to the prognosis; it was hopeless as regarded the recovery of sight. But still the case was a proper one for treatment—active treatment, too—it being a most important object to save the form of the eye, although it is destroyed as an organ of vision. Here was an eye affected with violent inflammation in consequence of injury: if the inflammation had been allowed to run on unchecked, it might have terminated in supuration and destruction; that is, bursting and collapse of the globe, and consequent falling in of the lids. Now a sightless eye, if of its natural form and size, is much less of a blemish; and hence, with a view of preserving this in Body, leeches were repeatedly applied, purgatives given, and the other parts of the antiphlogistic treatment adopted, followed by the exhibition of calomel in repeated doses, and the application of belladonna, in the hope of checking the progress of iritis, should it have existed, or of deeper-seated disorganizing inflammation.

Three days after admission the bluish turbidity in the anterior chamber had materially lessened; by the fifth had entirely disappeared; and now there was observed, deep behind the pupil, a greenish yellow colour, which by the eighth day had become uniformly saturated and yellow. From the first it was evidently not seated in the lens, which had either disappeared by absorption in consequence of rupture of the capsule, of which the bluish turbidity in the anterior chamber had in the first instance given some suspicion, or it remained and was perfectly clear and transparent. Now it was as certainly seen not to be seated in the posterior capsule, but deeper than this, possibly in the vitreous humour, but probably posterior to it. A small quantity of pus or lymph collected under the conjunctiva, at the part corresponding to the wound in the sclerotica, and evidently having exuded from within this coat. On being pricked with a cataract needle, a mere drop oozed out; this re-collected, but afterwards became less prominent, and gradually subsided.

On the sixteenth day after admission

the appearances as regarded the colour at the bottom of the eye were the same, but there was now for the first time observed several minute vessels running apparently over the substance on which the yellow colour depended, and directing their course from the periphery of the globe towards its axis; these increased in number, so as speedily to form quite a zone all round, apparently in a situation corresponding to the level of that of the posterior part of the ciliary body, or the anterior part of the vitreous humour, deeper than which the yellow substance consequently must have been. The redness of the conjunctiva and the sclerotica had now somewhat abated; the cornea remained clear; the pupil of its ordinary size; and the iris of its natural texture, but motionless.

The condition of the eye becoming stationary, and the lad anxious to get home, he was now made an out-patient, occasionally shewing himself, until his re-admission in December, when little or no change had taken place; the sole treatment in the interval having been irregularly taken doses of *hyd. c. creta*.

The history of this case, then, shews that the yellow appearance at the bottom of the eye, which was at one time presumed to be diagnostic of medullary disease, is not actually so; that this appearance may originate in inflammation, and in the deposition probably of lymph, in the situation usually occupied by the medullary growth. In this respect it confirms the observation of Messrs. Travers, Lawrence, and others, who have shewn that this deposition may not only originate in inflammation arising from injury, but in the same process taking place deep in the eye, unconnected with injury.

The subsequent progress of our case corresponded with one related by Mr. Travers, of a young lady wounded in the same situation as Body. In a short time after his re-admission, what I had for some time prepared you to expect took place—the globe diminished in volume; the cornea became less; the pupil contracted; in short, atrophy of the organ commenced, and was proceeding when he left the hospital.

The next case worthy of remark is that of Mary Falkner, *art. 25*, who was admitted on the 5th of February, on account of corneitis. The cornea of the left eye was the seat of an ulcer, occupying about one-fourth of its extent at the lower part. The ulcer was deep—had an irregular ragged appearance and yellow colour, as if the part had been subjected to maceration, and infiltrated with pus. There was very considerable redness of the sclerotic coat and conjunctiva, great pain, intolerance of light, and epiphora.

This patient had been confined in the Westminster Lying-in Hospital about a month previously, and shortly afterwards had been attacked with this affection in her eye, which, notwithstanding the treatment adopted, had become aggravated.

She was put upon low diet, purged, leeches repeatedly, and calomel in repeated doses was given, and belladonna applied round the eye, in case the iris was inflamed, which could not at first be satisfactorily determined. She complained much of an augmentation of pain at night, to obviate which, opiate frictions of the forehead were used.

On the fourth night after her admission, she had a very severe attack, followed by a sudden escape of watery fluid, and a sensation as if something had given way. The following morning I found that this had arisen from the ulcer having penetrated the anterior chamber, which was abolished, the iris being every where in contact with the cornea; but from this time the inflammation began to subside; the ulcerated surface lost its yellow appearance, and became clear and transparent. The previous treatment was persevered in, with the addition of a seton in the temple. On the fifth day after the ulcer had perforated the cornea, it was observed that the anterior chamber was re-established, and that there projected through the opening in the cornea a small transparent vesicle, constituting what is termed a hernia of the membrane of the aqueous humour, or keratocele, a condition dependent on the opening of this membrane having closed previous to that in the proper substance of the cornea, and being distended and protruded through the aperture in the latter, which takes a longer time to heal.

In the treatment of ulcer of the cornea, acute in its progress, as in the present case, the most efficient means are the antiphlogistic treatment, and issues in the temple. Calomel was given here, but this was done chiefly because it was dreaded that iritis also existed, for I do not attach so much value to its employment in ulceration of the cornea as to that of the ordinary depietory treatment. It has frequently been recommended that nitrate of silver should be applied in substance or in strong solution to the ulcer; but you will hesitate to resort to this in cases like the present, where the ulcer was so manifestly the consequence of acute inflammation, and not the cause of that under which the eye laboured.

When hernia of the cornea exists, how is it to be treated? We have been advised to snip it off, or to touch it with nitrate of silver. I recommend you to do neither; as the ulcer heals it will disappear, though no doubt the ulcer of the cornea

may, like ulcer elsewhere, exist for a considerable time. You saw how long this hernia was present in the case of Falkner (upwards of a fortnight), but that as the ulcer filled up and closed around it, it disappeared. But I have known it to persist for months. I was once consulted by an artist, in whom, according to the statement of the very intelligent surgeon who accompanied him, this affection had existed for four months. This gentleman had been subject every winter for several years to catarrho-rheumatic ophthalmia, the last attack of which had produced penetrating ulcer of the cornea. When I saw him, all inflammation had ceased for a considerable time; there was merely a very small ulcer of the part through which the hernia protruded, attended with inability to use the eye continuously. He was on his way to Italy, to pass the winter, in order, by a residence in that milder climate, to break the habit of those regular attacks of catarrho-rheumatic ophthalmia. The hernia in the cornea was not meddled with; in fact, nothing was done, but the ulcer ultimately healed, and the keratocoele disappeared, during his residence in Rome.

In the instance of Mary Falkner, the involuntary spasmodic action of the orbicularis palpebrarum muscle which existed on her entrance was greatly alleviated by the introduction of a solution of the extract of belladonna into the eye twice daily—a beneficial effect, which was even more strikingly evinced in the case of James Green. This boy, æt. 9, came in the 26th of February, with scrofulous ophthalmia in both eyes, but more especially the right. He was almost unable to open this eye, from the violent spasmodic contraction of the orbicularis muscle, and he was only a trifle better with regard to the left. So violent, indeed, had the action of these muscles been, that the integuments of the upper and under lids of both eyes had been brought into contact, and became extensively excoriated by their constant friction on each other, with great tendency to inversion of the lids. To remove the excoriation, a solution of sulphate of alum was employed, and that of the extract of belladonna was dropped into the eye twice a day, to relieve the spasm. The effect of the latter was most marked: in two days he could keep the eye open, unless when he spoke, and then the eye invariably became involuntarily closed, from the action of the muscle alluded to; but in two days more he was enabled to speak without this occurrence taking place, and at the end of a week he could keep his eyes open without difficulty. It may be noticed, that although the excoriation of

the eyelids has disappeared, the disposition to inversion of the lids has not yet entirely so; nor will this surprise you, when we are told that this disease of the eyes has continued for a period of four years, at which time he had the small-pox.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

March 26, 1829.

SIR B. BRODIE, BART. PRESIDENT, IN THE CHAIR.

Contributions to the Pathology of the Spinal Cord. By WILLIAM BUDD, M.D. [Presented by Mr. PERRY.]

THE author commences his paper by alluding to the investigations of modern physiologists respecting the functions of the spinal cord. The leading fact which these investigations have developed may be thus briefly stated:—When the spinal marrow of an animal is cut off from its connexion with the brain by decapitation or otherwise, and a stimulus is applied to the skin, the impression of that stimulus is transmitted to the spinal marrow, and being thence reflected to motor nerves, it causes contractions of various muscles. The part which the spinal marrow takes in this action has suggested the term “reflex function.”

The investigations of physiologists have consisted principally in experiments on the lower animals. It is the chief object of the present paper to shew that, under certain circumstances, the operation of the reflex function is exhibited in man in the same way as in decapitated animals. This is done by a series of cases of affection of the spinal marrow. The first case is that of a man, aged 43, who became gradually paraplegic, and had continued so fifteen months, when he came under the care of Dr. Budd. At that time there was a projection in the back, forming a vast abrupt tumor, and comprising the dorsal vertebræ from the fifth to the eleventh inclusive. Sensation in the lower half of the body began to fail at the umbilicus, and through the whole of the lower extremities it was nearly abolished. He had no power of voluntary motion over the lower extremities. When, however, any part of their skin was pinched or pricked, the corresponding limb jumped with great vivacity; the toes were retracted towards the instep; the foot was raised on the heel, and the knee flexed, so as to lift it off the bed. The limb was maintained in this state of tension for several seconds after the withdrawal of the

stimulus, and then became suddenly relaxed. Once or twice, while the left leg was thus excited, the great and second toes of the right foot were simultaneously drawn towards the sole. In those instances the pinching or pricking was perceived by the patient; but much more violent contractions were excited by a stimulus of whose application he was perfectly unconscious. When a feather was passed lightly over the skin in the hollow of the instep, as if to tickle, convulsions occurred in the corresponding limb much more vigorous than those induced by pinching or pricking. In these experiments he was quite unconscious of any thing touching the limb. No movements were excited in his lower extremities by tickling any point in the upper half of the body.

Similar convulsions were always excited by the acts of defecation and micturition, but they were then much more vigorous than in any other circumstances, so that the patient was obliged to resort to mechanical means to secure his person while engaged in these acts. The convulsions were at all times quite involuntary, and he was unable by any effort of the will to control or moderate them. The passions had no power of exciting convulsions. In the spring of 1837, voluntary power and sensibility began to return in the lower extremities, and the convulsive movements became gradually less violent.

In his remarks on this case, Dr. Budd observes there can be no doubt that these contractions were of the same nature, and excited by the same process, as those witnessed in a decapitated animal. Although sensation was never completely extinct in the lower extremities, it was quite evident that the convulsions were induced independently of its mediation; for when an artificial stimulus was employed, they were uniformly the most vigorous in that case in which its application was not at all perceived by the patient, namely, when the hollow of the foot was lightly touched with a feather. The fact that such vigorous convulsions were excited by touching the hollow of the foot with a feather, the author considers interesting, as tending to shew that the nerves which convey these impressions to the spinal marrow were, if not the same as those of true sensation, most actively excited by a mode of stimulus which produces strong impressions on the sensitive nerves.

The author gives two other cases of paraplegia, in which he observed the same phenomena; and a case of tetanus, in which violent convulsions were induced by the slightest touch of the patient's surface; he then subjoins the details of several cases of the same kind that have been

furnished him by Mr. Busk and Mr. Grainger.

The chief results to which these cases lead are—

1. That voluntary power has great influence in controlling these excited involuntary movements. Except in the case of tetanus, these movements were excited in the paralysed limbs only—were uniformly the most vigorous when the loss of voluntary power was complete—and diminished very rapidly as the patients regained the power of moving the limbs. At the first return of voluntary power, it seemed to require a distinct effort of the will to restrain the excited movements, but afterwards this appeared to be done unconsciously.

2. These excited movements may take place whether sensibility is destroyed or not.

3. Irritation of the integument of one leg generally caused movements of that leg only; in some cases it also caused movements, though in a much less degree, in the opposite leg, and in the arms when they also were paralysed. In one of Mr. Busk's patients, irritation of parts which were not paralysed induced involuntary movements in the parts which were paralysed.

4. Irritation of the soles of the feet is more efficacious in inducing movements of the lower extremities than that of any other part of the legs or feet, but not so efficacious in inducing movements of the upper extremities as irritation of the surface of the trunk.

5. The stimulus of heat acts very powerfully in inducing these involuntary movements. Its effect was tried in one of Mr. Busk's patients by means of a thick piece of metal made hot by immersion in water. When this heater was firmly placed against the soles of the feet, more extensive movements of the hands and arms were induced than by any other excitation. The convulsive movements continued as long as the heater was kept applied, or until the heat was dissipated. A similar instrument, at the ordinary temperature, did not produce any movements after the first contact. When ice was applied to the soles of the feet, it did not produce more effect than the simple contact of any other body.

It is singular that, in this case, when the heater was applied to the feet or legs below the knees at a temperature so great that its contact was painful to the hand, no sensation of heat was perceived by the patient, although the contact of the heater was distinctly felt. This seems to indicate a difference between the nervous filaments which convey the sensation of

contact, and those which enable us to appreciate temperature. The same thing was observed in one of Mr. Grainger's cases.

6. Strychnia acts very soon and very powerfully, rendering the involuntary movements excited in the paralysed parts more violent, without causing any increase of voluntary power.

7. The reflex function, like voluntary power, is liable to exhaustion; but the sense of fatigue seems to be associated with the exercise of voluntary motions only.

The author concludes by observing, that if we consider these cases for the sake of ascertaining the circumstances under which the phenomena in question are exhibited, we find, that with the exception of the case of tetanus, they all agree in one point—namely, complete loss of voluntary power, in consequence of injury of the pons varolii, or of the cervical portions of the spinal cord.

Since his attention has been directed to the phenomena of the reflex function, he has examined a great number of cases in which there has been hemiplegia, from hæmorrhage, or softening of the brain in one of the cerebral hemispheres, but has not, in a single instance, been able to excite movements in the paralysed limbs. It appears from this, that involuntary movements can frequently be induced in paralysed limbs, when the paralysis depends on some injury to the spinal cord above the lumbar vertebræ, but that they cannot be excited when the paralysis results from hæmorrhage.

WESTMINSTER MEDICAL SOCIETY.

Saturday, March 10, 1839.

DR. CHOWNE, PRESIDENT.

Discussion on the Finances of the Society.—

Dr. Bird on the Medus Operandi of the Carbonic Acid Gas in Cases of Poisoning.

THE first hour of this evening was occupied by an animated discussion on a proposal made by the Council, that for the future every member of the society should pay an annual subscription of one guinea. It appears the funds are at so low an ebb as to render such a measure as the present expedient. When the great knowledge and ability displayed in the debates of this society are considered, it will be admitted that its suppression would amount to an important professional loss; and that some energetic means should be adopted to prevent the occurrence of such an event.

At nine o'clock, Dr. Bird delivered an

excellent address on the subject of poisoning by the operation of carbonic acid. He dwelt upon the contradictory notions entertained by contemporary authors, as to the effects of this gas when inhaled into the lungs. He stated that the only correct sources of information as to the morbid changes produced, were extant in the German periodicals, in which official records were made of all deaths from poison, and the history of cases were drawn up by observers who had no theories to support. Dr. Bird confined himself this evening to a consideration of the question whether carbonic acid produced death by asphyxia, or by acting as a specific poison. He repeated the experiments of Collard de la Martine, and avowed himself a convert to the opinions of that physiologist. Collard argued, that if carbonic acid gas produced death by excluding oxygen from the lungs, like hydrogen or nitrogen, it ought to support respiration when mixed with the same proportion of oxygen as was contained in atmospheric air; thus, by mixing 21 parts of oxygen with 79 parts of carbonic acid, animal life should be supported equally well as in the atmosphere. To ascertain this, Dr. Bird went over the experiments of Collard. He placed a bird in a small glass vessel containing atmospheric air, for a given period (an hour); the animal was taken out uninjured. Another bird was placed in a similar vessel, containing a mixture of 79 parts of carbonic acid and 21 parts of oxygen, and the animal was apparently dead in seven minutes. When taken out, it did not recover. The proportions of the two gases being reversed, and the relatives being 79 oxygen to 21 carbonic acid, the bird died in twenty minutes. In five per cent. of carbonic acid, mixed with atmospheric air, death was produced in an hour after the bird was inclosed. The same kind of bird, when placed in an atmosphere of pure carbonic acid, is rendered insensible by asphyxia, and, if immediately drawn out, may be restored by being supplied with good atmospheric air. Dr. Bird and M. Collard infer from these facts, that the carbonic acid acts as a specific poison. The experiment of Sir Benjamin Brodie was rendered inconclusive, Dr. Bird said, by the too rapid introduction of the carbonic acid, which asphyxiated the animal by producing closure of the glottis; and the subsequent recovery of the bird was accounted for by its restoration to a wholesome respiratory medium. Dr. Bird considered the contents of atmospheric air vitiated by the combustion of carbon, to consist of atmospheric air, free carbonic acid, and disengaged nitrogen. Certain German chemists enumerated carburetted hydrogen and a little cyano-

gen amongst the constituents; but Dr. Bird had not himself detected any of these ingredients. He thought that what they denominated carburetted hydrogen was nothing but wood smoke, which, though having an unpleasant odour, was by no means the most dangerous constituent in these vitiated atmospheres. The carbonic acid projected into the atmosphere by the slow combustion of charcoal, possessed no sensible properties, and was therefore the more dangerous. Dr. Bird now shewed that the slow combustion of charcoal in which no mirage was produced, was more copiously productive of carbonic acid gas than a more vivid combustion, in which there exists a very obvious mirage. In the first case, too, the temperature of the gas produced is scarcely higher than that of the circumambient air, and it consequently does not ascend, but by its gravity intermixes with the lower strata of the air. In the second case, the rapid combustion is attended, of course, with a high temperature; the heated gas ascends, and is distributed more equally through the chamber. Dr. Bird related the poisoning of the congregation, which occurred in Downham church, from the use of a charcoal stove, and proved by the details that the destructive effects of the gas are evidenced first within a certain circuit from the stove. He then considered at length the *modus operandi* of the poison, which, he thinks, first affects the nervous fibrils distributed in the serous lining of the blood-vessels. He then entered into a number of interesting details, which have already appeared in the *MEDICAL GAZETTE*. The address was received with great marks of approbation, and, on the motion of Mr. Snow, the ensuing Saturday evening was devoted to the discussion of the subject.

Saturday, March 23d.

FREDERICK HALE THOMSON, Esq.
IN THE CHAIR.

*Fibro-Albuminous Tumor of enormous Size.—
Medullary Sarcoma.—Melanosis in all the
Textures of the Body.*

Mr. Davies laid before the Society a large fibro-albuminous tumor of the ovary, which he had extracted from the body of a woman 68 years of age. The tumor weighed 23 pounds, and had been fourteen years in growing to its present magnitude. Mr. Davies had divided it through the middle, and its structure was generally fibrous and hard, but certain spots existed of softer consistence than others, and two discs were evident, of about the size of half-crown pieces, where the substance had very much the character of fungus hæma-

todes. There also was one cavity large enough to hold a duck's egg, which had been filled with a serous fluid. The spermatic arteries had grown to twice their natural size, and the spermatic veins to four times their normal capacity. The cavity of the uterus was filled with a similar growth to that in the ovary, and that viscus was distended to the size and shape of a cricket-ball. The patient had had no children for thirty years; she experienced no pain, but merely a sense of weight, during life. She had had formerly a prolapsus uteri, which, however, was removed as the tumor increased in size.

Mr. Hale Thomson now related a case of medullary sarcoma in the diploe of the frontal bone. Henry Davis, æt. 12, admitted into the Westminster Hospital October 30, 1838. He had a hard red tumor on the left breast, which had a slight pulsatory feel. It was first perceived six months previous to his admission, and gradually increased to the size of a walnut: his general health was good, although he had felt pain in the side as long as he could remember. Leeches and fomentations were applied to the swelling, and the following mixture ordered:—

Potass. Hydriod. 3ss. Iodin. gr. ij.
Aque destill. ʒviij. Cap. Coch. i.
med. ter die.

In a few weeks the malignant nature of the disease became manifest, three fungoid masses presenting themselves through the parietes of the chest: he sunk exhausted five months after his admission. On examining the chest, it was found entirely occupied on the left side by a mass of medullary sarcoma. The left lung was nearly obliterated, and the heart pushed quite to the right side. In the centre of the frontal bone the disease was fully established in the mediotullium, but in no other part of the head. The brain was quite natural. The heart had three small tumors in it, and the right lung was studded with sarcomatous deposits. The beat of the heart during life was of course felt on the right side.

After the members had carefully examined the sternum and the thoracic viscera, which Mr. Thomson had brought forward, the President also exhibited two specimens of malignant disease of the cranium.

Joseph Nugent, æt. 40, sent to the Westminster School of Medicine for dissection: his last place of abode was the Strand Union Workhouse, where he died Feb. 11th, 1839. The certificate of the cause of death was consumption. No previous history of the case had been obtained. The whole surface of the chest and abdomen presented a speckled ap-

pearance, the integuments being raised by small melanotic tumors. On dissection, it was found that melanosis pervaded every structure of the body. The subcutaneous cellular tissue and the glands of the axilla were loaded with masses of the disease. The peritoneum was thickly studded. The brain and its membranes were involved throughout their whole surface, and tumors as large as walnuts were found in the medullary substance of the cerebrum. Small melanotic spots were found in the substance of several of the nerves, especially in those of the upper extremities. The bones of the cranium and pelvis were much affected with the disease, and it occupied the cancellous structure of the parietal bones particularly. Cruveilhier, in his valuable work, *Anat. Pathol. du Corps Humain*, has published a plate, shewing this disease as it affects the skin and cellular tissue; and any one seeing the subject brought into the Westminster dissecting-room, would imagine it the *fac simile* of the one from which Cruveilhier took his drawing. Mr. Thomson now handed round one of Cruveilhier's plates, on which melanosis of the surface of the body was represented.

Dr. Addison congratulated the Society on the number of morbid specimens which were presented for its inspection: this augmented attention to morbid anatomy must have good effects. No one had yet succeeded in defining the limits of malignant tumor. This fact, he thought, should be considered as an opprobrium on the profession; for it was evident that a little systematic inquiry would supply this desideratum. He might suggest, that the rapidity with which a tumor was formed afforded a good index as to its malignant or innocent character. Malignant tumors were generally of rapid development.

At nine o'clock, the hour appointed for the discussion on Dr. Bird's interesting paper "On poisoning by Carbonic Acid," a vivid discussion took place as to certain alterations in the constitution of the Society, proposed by the Council, and the discussion on the scientific subject was therefore postponed to the same hour on the ensuing Saturday.

1810s.

PHYSICAL SOCIETY, GUY'S HOSPITAL.

March 23, 1839.

MR. GREENWOOD IN THE CHAIR.

Paper and Discussion on Curvatures of the Spine.

MR. CHAPMAN, of Tooting, read a paper on spinal curvatures.

The President drew attention to the

several points touched upon by Mr. Chapman. That gentleman had confined his remarks to lateral curvatures occurring in the earlier periods of life, and not depending upon disease of the vertebræ or ligaments, but referrible rather to an enfeebled state of the muscles that support the spinal column. He had reprobated undue restraint, such as stiff stays, for the cure; he had objected to restrained postures, and unnatural mechanical appliances; he had recommended nutritious diet; ease of body; a free reliance upon the efforts of nature, aided by moderate calisthenic exercises; and attention to the general health. He had not entered into pathology, but had given the following as the principal remote causes of these lateral curvatures in young persons. "Want of air and exercise, want of sufficiently nutritive diet, want of sufficient repose, want of sufficient mental recreation, want of attention to the due performance of the natural functions; the loss of muscular power produced by tight bandages in the form of stays; and the prevalence of any habit or custom having a tendency to reduce the powers of the system below their natural and healthy standard." These points were severally worthy of discussion.

Mr. Iliff reported the case of a child two or three years old, a patient of his; there was a small projection in the back when he first was called in, and he had prescribed good diet, and attention to the general health, in preference to mechanical agents. Its parents, however, becoming impatient in a very few weeks, consulted the late Dr. Harrison, under whose entire management, compression, thumbing, recumbent position, &c. were persevered in for three years, and the child is at this moment very much emaciated and decrepit.

Mr. Leadam had seen several cases treated by Dr. Harrison which had turned out very differently to the one mentioned by Mr. Iliff. The patients were girls, of 16, 17, 18, and 19 years of age; and not only had the spinal curvature straightened, but the general health, moreover, had become remarkably established. He saw two cases treated upon the principles advocated by Mr. Chapman, without success; these were completely restored under Dr. Harrison.

Mr. Chapman allowed that mechanical means might be advantageous in some cases under judicious medical superintendence, but he objected to their application empirically, in every case indiscriminately. There was an establishment near Paris for the reception of spinal deformities, to the manager of which a prize had been given by the Institute of France

for the great success that had resulted to his patients under the plan of treatment recommended by himself to-night.

Mr. Hiff alluded to the plan of the late Dr. Cheshire, of Hinckley, who was in great repute some years ago. Steel supports passed from the pelvis to the head, and constituted the principal mechanical means employed; but in Mr. Hiff's opinion, good regimen, the salubrity of the climate, country amusements, and attention to the general health, were the more important parts of the curative treatment.

Dr. Hughes objected to a statement made by Mr. Chapman, that the higher classes of society were more liable to deformed spines than the poorer, for he had extensive opportunities for observation in a large dispensary practice, and daily witnessed deformities and spinal curvatures, especially about the lumbar region of women, arising, no doubt, from hard work, carrying children, poor living, and the like. He called to mind a case which, three or four years ago, was a picture of misery, from strumous ophthalmia, porrigo capitis, curvature of spine, swelled hips, and grievously out of health. Many unsuccessful attempts at cure had been made. Dr. Hughes recommended all stays and restraining bandages to be removed; he prescribed iodine with a bitter infusion, country air, sponging the back, &c. At the present date that child is perfectly well.

Dr. Ashwell said there were many difficulties in determining the proper treatment and management of spinal curvatures, and medical men had encountered no small degree of opposition in persuading the public not to consult quacks. But of late, great improvement had taken place, principally in the dietetic part of the treatment; wine, porter, meat, and generous food, being now allowed, where formerly they were totally prohibited. He remembered Dr. Cheshire's treatment, having, like Mr. Hiff, been at one time a resident in that part of the country; but there was something radically wrong in his plan; for the support to the back being from the pelvis to the head, whenever it was removed, the spine, having had no opportunity of acquiring strength by proper exercise, gave way, and the ultimate condition of the patient was worse than ever. The best proof of the futility of this system is, that it is now quite exploded. In the treatment of spinal curvatures Dr. Ashwell approves of generous diet, and strongly recommends the support made by Mrs. Hart, as originally invented by Mr. Callum, a medical man. This support passes from the hips to the axilla, interferes with none of the moderate exercises

of the individual, is worn under the garments without inconvenience, and proves highly beneficial. Sir Astley Cooper uses this apparatus very frequently. Dr. A. has seen the calisthenic system tried, but not with the degree of success mentioned by Mr. Chapman. Mischief has sometimes resulted from undue exercise. He was also opposed to Dr. Harrison's plan of making compression, for in two cases paraplegia was super-induced, and in others the result has produced puny and decrepit bodies.

Mr. Chapman admitted that the hardships and privations of the poor in large cities tended quite as much to produce spinal deformities as the educational restraints and luxurious habits of the rich; in both cases the healthy and natural functions of the body being interfered with. But had Dr. Hughes ever seen a crooked housemaid, or a deformed country wench? A little girl, a relative of his own, about 14 years old, was the subject of a double spinal curvature. He received her into his house; there she amused herself with a child of his own, unrestrained; exercise and amusement were freely indulged in; good food was allowed, with wine and porter; and in six months she was quite well. Exercise tends greatly to strengthen and develop the muscular support of the spine. Swimming, though scarcely practicable by females, was an exercise tending to much advantage in this respect.

Mr. Hiff referred to the bent limbs of children, which so constantly straighten without splints, in further and analogous corroboration of the power of nature.

Mr. Henry had under his care a case of deformity following small-pox; the body was covered with boils, the health was deranged, and nearly every bone seemed bent. Pressure and splints were at first tried, but produced no advantage. He now fell back upon beef and mutton, and other good living, and his patient is at present nearly well. He objected to any regular system of gymnastics, because it was impossible to measure the quantity of exertion proper for every individual, but prefers leaving children to their own natural inclinations upon this point; they should also go early to bed, and always lie upon hard beds. Mr. Henry expressed a very unfavourable opinion of the plan by compression practised by the late Dr. Harrison, and considered it deficient in scientific principle.

Mr. Gaslee said it was not surprising that quacks had hitherto been much resorted to for the cure of spinal affections. The length of time required for treatment rendered friends too often impatient of orthodox measures, and induced them to

give credence to the delusive promises held forth by empirics; but it was gratifying to observe that, as this class of complaints was each day better understood by medical men, quackery was losing its influence over the public mind. From the earliest period of life children are liable to curvatures in various parts; these evidently depend, in the immense majority of cases, upon an imperfect solidification of the bones, a state analogous to a degree of mollities ossium. In the cases empirical mechanical treatment must be wrong, for that could not cause a secretion of phosphate of lime to take place in the bones in order to strengthen them: here general principles are applicable. In older life curvatures occasionally result after measles, small-pox, or other accidental febrile ailments: here, also, general principles are required, for mechanics alone can give no permanent strength to such bones. Under medical supervision, doubtless, mechanical apparatus may now and then be of service, but only as an adjunct to general treatment. Mr. Gaselee rather objected to a system of calisthenic exercise, as too extreme a measure for the general run of cases.

Mr. Leadam disclaimed any particular partiality for the principles of the late Dr. Harrison; but having seen advantage to result under his treatment, he had deemed it fair to acknowledge it. There was a material difference between the curved limbs of children and the bent spines of growing persons; the former was a softened state of the bones; the latter, as he believed, an affection of the ligaments. He quite agreed that mechanics can do nothing for cases of the former kind.

The President said that it behoved medical men, as guardians of the public health, to caution parents against the system of stays and restraints to which girls were subjected in the present day, in the process of education. Every sacrifice was made to what was termed "improvement of the mental faculties," regardless of the injury to bodily health that resulted thereby. The system of diet, too, in schools was peculiarly objectionable, and tended to promote those spinal deformities and other derangements of the constitution which were so commonly met with in such places.

Mr. Chapman made a few observations in reply, after which the Society thanked him for his obliging communication, and adjourned.

At next meeting, Dr. Babington in the chair, Mr. France will introduce the subject of Gangrene.

PARISIAN MEDICAL SOCIETY.

THIS society held its anniversary dinner at Lawson's hotel, Rue de Rivoli, on Wednesday last, the 13th inst. In addition to the members, comprising most of the British medical men now in Paris, were present several of the professors of the faculty, and of the hospital physicians and surgeons of Paris—including Professors Moreau, Fouquier, MM. Louis, Ricord, &c. A letter was read by the chairman from Professor Andral, expressing his regret that a professional call from Paris prevented his attendance. Dr. Mott, of New York, was also unfortunately absent in consequence of indisposition.

The president of the society, Sir R. A. Chambers, M.D. K.H., took the chair. The company consisted of 60 professional gentlemen, nearly all of whom are members of British and foreign universities. After an excellent dinner, the chairman rose and gave Her Majesty Queen Victoria, which toast was enthusiastically received. Next followed the health of the Queen Dowager and the royal family of Great Britain, which was likewise warmly cheered.

The health of the King of the French and the royal family of France was next given, and being greatly applauded, Professor Moreau rose and stated that he would not fail to make known to his royal master the cordial manner in which the toast has been drunk.

In rising to propose the next toast, "The Prosperity of the Society," the Chairman addressed the company as follows:—

Gentlemen,—I have now the satisfaction to give you another toast, which I feel confident you will likewise receive with pleasure, and drink most cordially: it is one more immediately connected with our present social meeting, and I beg permission to preface it by a few words.

It is, I presume, known to most, if not to all of you, gentlemen, that about a year since a laudable zeal for the cultivation of science generally, for the honour and advancement of our profession in particular, and a conviction of the numerous advantages which might accrue to both by an occasional union of their cultivators, induced a few British medical gentlemen, some of whom I have the pleasure to see now present, to follow the example of nearly all the great medical schools, and to attempt the establishment, in this capital, of a society, with a view to discuss medical questions in their own language, and to bring together, as much as possible, the scattered advocates of various theories and modes of practice who resort hither from every school, in order to extend their knowledge, and to test the truth of their

opinions. (Hear, hear.) These meritorious exertions have met with a success beyond what could have been anticipated, when the difficulties, now happily surmounted, are considered (Cheers.) The society has thus been formed, and the great interest that has, during the last six months, accompanied the debates, both in a practical and theoretical point of view, has led to a desire on the part of the members that the society should rank among the permanent institutions of Paris. (Repeated cheering.) From as small beginnings as these, gentlemen, great societies have sprung. (Hear, hear, and cheers.) Let us therefore indulge a hope that ours, as yet in its infancy, will, in time, through your fostering care, and under that of future members, contribute its share in exercising a beneficial influence over the progress of our art—an influence which, beyond doubt, has marked the career of the older and more celebrated societies of Europe. (Great applause.) I give you, then, gentlemen—

“The Parisian Medical Society, and permanent success to it.” (This toast was received with immense cheering, which lasted several minutes.)

The Croupier, Dr. M'Moran, vice-president of the society, gave—

“The Universities of Great Britain, Ireland, and France,” which he prefaced by a proper eulogium upon these time-honoured institutions.

The secretary, Mr. Acton, in proposing the medical institutions of the same countries, paid a well-merited tribute to the liberality of those of France, which had, in fact, been the cause of the very existence of the society.

Mr. Wane then gave the health of the chairman, and dilated at length upon his private and professional merits, and his public services in the Peninsular, &c. campaigns; and called upon the company to express their warmest thanks for the public spirit with which he, the chairman, had contributed his utmost to the establishment and the support of the society.

MM. Moreau, Louis, and Ricord, on their healths being drank in connexion with several French medical institutions, expressed their great gratification at seeing evinced by the present meeting, that so much cordiality and brotherhood existed between the members of the profession in the two countries, and hoped that one great object—namely, the discovery of truth—would ever unite the learned in all nations.

After several other speeches, from Dr. Bennett, Mr. Strange, Mr. Dundas, Mr. Bennett, M. Ricord, Mr. Hey, and others, principally expressive of the great benefits

which science in general, and medicine more particularly, derive from societies like this, the meeting broke up; having given satisfactory proof, by the cordiality and good feeling which had existed throughout the evening, that the society was now established on a firm and permanent basis.

EXTRACTS

FROM THE PROCEEDINGS OF THE PATHOLOGICAL SOCIETY OF DUBLIN.

ENCEPHALOID TUMOR OF THE ABDOMEN, WITH OBLITERATION OF THE VENA CAVA.

Dr. GRAVES exhibited an abdominal tumor, which lay upon the upper part of the aorta and vena cava. The front of the latter vessel was almost completely incorporated with the cyst of the tumor, and its interior was obliterated by a substance quite analogous to that of which the tumor was composed. In this case the tumor had a distinct, but not diastolic pulsation, accompanied by bruit de soufflet, while the patient lay on his back, which ceased when he assumed the erect position. The left epigastric, mammary, and intercostal veins, were in a varicose condition. (Museum, Park Street.)

FRACTURE OF THE TIBIA AND FIBULA; WITH LACERATION OF THE ANTERIOR TIBIAL NERVE, PRODUCING SEVERE NEURALGIA OF THE LEG.

Mr. Smith presented to the society a preparation, shewing an oblique fracture of both bones of the leg, united with considerable deformity. The anterior tibial nerve had been torn across. The extremity of the upper portion of the nerve had become adherent to the upper fragment of the tibia, while the lower portion, along with the tendons of the extensor muscles, was united to the extremity of the lower fragment of the bone.

The long-continued existence of neuralgic pains, of a severe character, rendered amputation necessary two years after the receipt of the injury. The neuralgic pain extended from the knee to the seat of fracture; the limb below this was nearly destitute of feeling. (Museum, Richmond Hospital.)

DISEASE OF THE SCIATIC NERVE.

Mr. Carlile exhibited a specimen of disease of the sciatic nerve. A tumor, about three inches in length, occupied the upper part of the nerve, apparently formed by several successive depositions in and upon the substance of the nerve; a second, of smaller size, was seated a little above

the division of the nerve; and at intervals along its trunk were several smaller nodules, some lying on the surface, others in the centre.

The interior of the nerve presented a striated appearance, from the intermixture of the morbid structure with the original texture of the nerve. The plantar muscles resembled the surrounding cellular tissue in colour, and were soft and flaccid; the specimen was taken from an adult female, who had never complained of pain along the course of the sciatic nerve, or any of its branches, but had lost the power of walking. (Museum, Park Street.)

CYSTS CONTAINED IN THE PARIETES OF THE HEART.

Mr. Bigger exhibited a heart, the parietes of which contained a number of cysts, about the size of a small bean: some were merely inserted between the carneæ columnæ, while others were imbedded in the muscular substance of the heart, particularly towards its apex; they contained a fluid of a purulent aspect; the patient from whom the preparation was taken died of phthisis pulmonalis, and never complained of any symptom connected with disease of the heart.

OBILITERATION OF THE ABDOMINAL AORTA, THE LEFT ILIAC AND FEMORAL ARTERIES.

Mr. Hutton exhibited a preparation, in which the abdominal aorta, for two inches above its bifurcation, the left iliac, and femoral arteries, were filled with fibrine; the lining membranes of the iliac and femoral vessels were here and there vascular and thickened, but the coagulum was not connected to the vessel by any false membrane; the coagulum in the aorta was deprived of colouring matter, and contained a small quantity of thick purulent fluid in the centre; its lining membrane presented no signs of inflammation; the iliac and femoral veins were also filled with coagula, but did not appear to be inflamed.

The individual had died of gangrene of the extremities, affecting in the first instance the left foot; the process of obliteration of the left iliac artery was distinctly traced during life; the gangrene of the right lower extremity did not begin until after the obliteration of the aorta.

CONTAMINATION OF THE FŒTUS BY VENEREAL POISON.

Dr. Evory Kennedy presented a fœtus exhibiting the characteristics of venereal taint, and born about the sixth month, the mother being affected with decided syphilis, which had been contracted, according to her statement, about two months previous to the birth of the child.

Dr. Kennedy observed, that if the mother's statements were to be believed, they would go to establish the communication of syphilis to the fœtus in utero in an advanced stage of its development.

PECULIAR ULCERATION OF THE EYELIDS, EXTENDING TO THE BONES OF THE NOSE AND ORBIT.

Mr. Smith exhibited a cranium, shewing the extensive ravages committed by a peculiar form of ulceration, which began in the lower eyelid; the entire of the malar and maxillary bones of one side had been destroyed, as had also large portions of the frontal, ethmoid, sphenoid, nasal, lachrymal, and spongy bones; the mouth, orbit, and nose, formed one immense cavern, which communicated with the cavity of the cranium by a large perforation in the orbital plate of the frontal bone. Mr. Smith also presented drawings illustrating the partial progress of the disease, from its commencement up to its fatal termination; he mentioned the characteristic feature of the ulcer, and referred to the description given of the disease by Dr. Jacob, in the fourth volume of the Dublin Hospital Reports. (Museum, Richmond Hospital.) — *Dublin Journal of Medical Science.*

BALSAM OF COPAIBA IN DYSENTERY.

INFLUENCED by a consideration of the beneficial effects of copaiba in diseases of some of the mucous membranes, and by the testimony to its utility in dysentery borne by Pemberton, Cheyne, Good, Armstrong, Abercrombie, and other British authorities, Dr. La Roche, of this city, was induced some years ago, to resort to this balsam in a case of dysentery which had proved intractable to the ordinary means. "The effects obtained were," he says, "such as to encourage me to make further trials of the remedy; and after duly reflecting on the issue of those cases, and on the phenomena presented, not only in obstinate but in ordinary cases also, I have no hesitation in expressing the opinion, that, so far as my experience goes, the copaiba is entitled to the praise it has received, and consequently deserves a trial in some forms of the disease in question. It is hardly necessary to say," he adds, "in the present state of our knowledge respecting the uncertainty of the action of medicinal agents generally, that the copaiba cannot be expected to succeed in every case, and that it should not be prescribed in all stages of the complaint. Like other remedies, it will, in this disease, as in other forms of mucous inflammation, often fail, even when used

under the most appropriate circumstances; and, so far as I can decide, it would be improper to have recourse to it in the commencement of the attack, before the violence of the inflammation has been reduced by general and local depletion, by diluent drinks, tepid baths, fomentations, mild purgatives, ipecacuanha, opiates, emollient injections, and blisters."

But even in cases in which depletion has been premised to reduce the force of the inflammation, some discrimination is necessary as regards the employment of the copaiba, because it sometimes disagrees with the stomach, producing nausea and vomiting. When this is the case the remedy must be discontinued.

"Judging from what I have had occasion to observe," Dr. La Roche further remarks, "I think I may safely say, that the balsam is as serviceable in the secondary stages of acute dysentery as in the chronic form, and that it will be found particularly useful when the stools are rather copious, and contain a large proportion of mucus, or glairy matter, mixed with blood. When the griping and tenesmus are still very severe, it will be necessary to combine the medicine with a portion of opium; otherwise it may be used without, in an aromatic mixture—in cold water, or in an emulsion. The opium also may be required if the copaiba disorders the stomach, and if this effect can justly be attributed to the simple irritability of that organ. In general it is advisable to give the copaiba in moderate and repeated, rather than in large doses; as it is thus less apt to produce griping pain, to purge, and to increase fever. But whether the quantity be large or otherwise, no time must be lost in suspending its use if the symptoms of increased gastro-intestinal irritation and febrile excitement supervene.—*American Journal*.

HOW TO GET RID OF A PATIENT.

THE town of Basle has lately lost Dr. L. P. Stickelberger, aged eighty-one, the senior member of the faculty of medicine. He enjoyed a great reputation, acquired by immense knowledge, long experience, and indefatigable zeal in the practice of his profession. Dr. Stickelberger was as eccentric as he was learned and humane. One day being wearied by the complaints of an old woman who had accosted him on the middle of the bridge over the Rhine, in order to set forth all her numerous ailments, he told her to put out her tongue, and shut her eyes, and when the docile patient had obeyed his prescription, he quietly withdrew, leaving her with her mouth open.—*Gazette des Hôpitaux*.

ACUPUNCTURATION.

To the Editor of the *Medical Gazette*.

SIR,

MAY I beg permission to correct an error or two into which your correspondent "Lector" has fallen, touching my communication on Acupuncture.

1st. I do not claim for Mr. Hunter the credit of having first introduced acupuncture as a remedial agent into these countries; but I do claim for him the merit of having first introduced it as a substitute for the highly dangerous practice of scarifying, with the lancet or scalpel, anasarous extremities; and I conceive no better proof is required than that such practice was unknown to Sir B. Brodie, and I presume also to the learned author of the *Surgical Dictionary*, from whose extensive learning, so valuable an improvement could scarcely have failed to be noticed, had it been known to the profession.

2d. If "Lector" will revert to my note, he will see that I do not in the least insinuate that Dr. Graves had appropriated this beneficial improvement to himself. My object was to state the source from whence we had received this very decided improvement, and to give the honour to whom, I believe, it is justly due.

I am, sir,

Your obedient servant,

J. ARMSTRONG.

Gravesend, March 21, 1839.

WEEKLY ACCOUNT OF BURIALS.

From BILLS OF MORTALITY, Mar. 26, 1839.

NOTICES.

We can have nothing whatever to do with Dr. Warburg's "Specific Drops for Fever." Let him tell what they are, and how they are prepared, and we may then possibly be induced to try them.

We are obliged to postpone the Medical Missionary Society in China till next week.

WILSON & SON, Printers, 57, Skinner-st., London.

[EXTRA LIMITES.]

OBSERVATIONS

ON

AN ARTICLE CONTAINED IN THE DUBLIN JOURNAL OF MEDICAL SCIENCE FOR JANUARY 1839 (BEING NO. 42), INTITLED,

"An Examination of Dr. Hamilton's Letters in defence of his Opinions, especially in reference to the Management of the First Stage of Labour."
By EDWARD W. MURPHY, A.M., M.D. late Assistant Physician to the Dublin Lying in Hospital."

Addressed through the medium of the LONDON MEDICAL GAZETTE to the readers of the DUBLIN JOURNAL OF MEDICAL SCIENCE.

By JAMES HAMILTON, M.D.

Professor of Medicine and Midwifery, &c. in the University of Edinburgh.

DR. HAMILTON most reluctantly feels compelled to make a public complaint against the Editors of the Dublin Journal of Medical Science. In doing this he is not actuated by the sole motive of defending himself against what he considers gross injustice (for in his station such considerations are of little import), but by an anxious wish to endeavour to deter those editors from acting in the same manner to individuals who may not be so independent of their censure or their praise as he feels himself to be.

In that journal, No. 37, there appeared an article by Dr. Collins, misrepresenting some published opinions of Dr. Hamilton. The editors readily admitted a reply; but they subsequently received and published an article from Dr. Collins, most discreditable, not only to him, but to their own journal. On this article Dr. Hamilton felt it his duty to animadvert, and at first the editors refused to admit his reply, on the allegation that they did not wish to continue the controversy; apparently, however, conscious of the injustice to such a proceeding, they afterwards agreed to insert it, and accordingly it appeared in the number for November, 1838.

In that reply Dr. Hamilton concluded by declaring that it was impossible for

him to have any further communication with Dr. Collins, thus, as he believed, putting an end to the controversy.

The reader may judge of his surprise when he found that the editors of that journal had admitted in their number for January 1839, an article by Dr. Murphy, formerly assistant to Dr. Collins, reiterating all the calumnious charges against Dr. Hamilton's opinions, and defending some practical precepts of a most dangerous tendency, which are advocated, and had been fatally acted upon, by Dr. Collins.

It became Dr. Hamilton's duty to reply to this new controversialist, and accordingly he wrote the following pages, and sent a proof copy in print to the editor of the Dublin Journal of Medical Science, from whom he received a letter, dated March 6, "respectfully" declining the insertion of his article. Before being favoured with that communication, he had learned that the Dublin Journal for March 1839 contained a long tirade from Dr. Collins, which, of course, Dr. Hamilton is precluded, by his recorded declaration, from ever looking into. He put it, however, into the hands of two intelligent friends, who stated (after bestowing an epithet upon it which he does not choose to repeat), that it was utterly unworthy of notice.

The charge which Dr. Hamilton now feels himself warranted in making against the editors of the Dublin Journal of Medical Science is, that they have given insertion to observations misrepresenting and falsifying his doctrines, and have refused to allow him an opportunity of defending himself. And he has a still more serious charge to prefer against them, viz. that of sanctioning the mis-statements of Dr. Collins and Dr. Murphy, and, by endeavouring to suppress Dr. Hamilton's exposition of the dangerous tendency of their practical precepts, of misleading the inexperienced practitioner of Ireland, and thus do incalculable mischief.

Following the example of the late Dr. Gooch of London, Dr. Hamilton published, in 1836-7, for the information of the profession, the result of his experience,

B*

under the title of Practical Observations upon various subjects relating to midwifery.

The object of that work was to state the reasons which had induced Dr. Hamilton to consider the ordinary practice in many cases of difficult and dangerous to be erroneous, and to suggest certain changes, the utility of which had been confirmed by his experience. While he undertook this task he did not anticipate that he could have been suspected of intending to represent those who continued to pursue the practice to which he objects, as either ignorant or prejudiced. He was quite aware that it is the duty of medical men, when they enter on the exercise of their profession, to adopt the rules which they have been taught; and he was equally aware that not a few continue to pursue the same routine, inattentive to the varieties and phenomena of human disease.

In the second part of his Practical Observations, Dr. Hamilton has noticed and animadverted upon (as it was his right and his duty to do) the opinions of Dr. Osborne, Dr. Denman, Dr. Davis, Dr. Burns, Dr. Dewees, and other esteemed authors; and when it was actually in the hands of the printer, Dr. Collins's Practical Treatise was sent to him by his bookseller. He considered it incumbent on him to notice that work, on account not only of the respectable station which Dr. Collins had held, but also of the valuable practical information it communicates. Dr. Hamilton has given all due credit to Dr. Collins for the candour and value of his records, and in dissenting from him on practical points, has endeavoured to use the most respectful language.*

The reader may therefore judge of Dr. Hamilton's surprise when he found, in the Dublin Journal of Medical Science for March 1837, an article by Dr. Collins, containing animadversions on the doctrines of his Practical Observations, founded upon most erroneous views, and

containing most ealumnious charges against his practical precepts, alleging "that they are calculated to urge junior practitioners to a hasty, unnecessary, and consequently injurious interference," and holding them out "as cruelly encouraging the destruction of the child,"—"as being fraught with much hazard to the patient," &c.

An attack so unexpected and so uncalled for, necessarily compelled Dr. Hamilton to point out the mis-statements, and to endeavour to prove that his precepts, instead of being of the dangerous tendency asserted by Dr. Collins, are confirmed by the cases published by that individual himself, as satisfactorily as if those cases had been fabricated for the express purpose. At the same time he declared, that if his opinions had been fairly quoted, he should have left the profession at large to judge of their validity. This Dr. M. has called, "*inviting a controversy*," and "*a novel mode of proceeding*."

Indeed!—defending himself against misrepresentations and calumny, is held out as "*inviting a controversy*," and "*a novel mode of proceeding*!"

When Dr. Collins, by garbled extracts, substitution of words, and the interpolation of expressions not contained in the text, deliberately misrepresented Dr. Hamilton's opinions and precepts; and when, upon those manufactured misrepresentations he founded most injurious accusations, could it have been imagined that Dr. Hamilton should submit tacitly to such conduct? And when it is considered that the only possible object which could have induced Dr. Hamilton to publish his Practical Observations, was a conviction that the result of his experience might benefit the profession, and of course the public, it would have been a most extraordinary circumstance, if Dr. Hamilton had not stepped forward to rebut Dr. Collins's charges.

The notice which Dr. Hamilton was thus compelled to take of the cases which had occurred in the Dublin Lying-in Hospital, it appears has had an effect which he had never contemplated. It has impressed on the minds of Dr. Murphy and his late master, the delusion that Dr. Hamilton's object was not to defend himself from misrepresentations and calumnies, which is really the truth, but to censure the practice adopted during their incumbency in the Dublin Lying-in Hospital.

Any argument addressed to persons under such a delusion*, would be labour

* In consequence of this hurried reference to the Practical Treatise, Dr. Hamilton fell into a very unintentional error, which he has noticed in his letter dated July 4th, 1837, to the editor of the LONDON MEDICAL GAZETTE, paragraph 27, in the following words:—"In illustration of my objections to Dr. Collins's rule, I referred (in the 2nd part of my Practical Observations) to several of his recorded cases; and I find that in doing so I had committed a gross error, for which an apology is due. This error, which was most unintentional, can be readily accounted for. I had made a memorandum of all the cases (in his work) in which it appeared to me that there had been an injurious delay in affording assistance; and I had afterwards selected the cases where there had been disproportion, but I had forgotten to mark off those latter, unluckily; therefore both lists were printed, the original one in page 105, and the selected one in page 162. Under the hurry of my professional duties, this and several other typographical errors were overlooked."

* The reader will find proofs of this delusion through the whole of Dr. Murphy's article; but it is fully avowed in page 439, Dublin Medical Journal, No. xlii.

lost; but as they have published their complaints, it is incumbent on Dr. Hamilton to give some explanation to the readers of the Dublin Journal of Medical Science.

Firstly, Had Dr. Hamilton undertaken to review the "Practical Treatise," and had he selected a few of the worst managed cases as proofs of the usual treatment of patients in the Dublin Lying-in Hospital, then, indeed, there might have been cause for complaint. But instead of this, every case referred to by Dr. Hamilton serves to illustrate those precepts which Dr. Murphy and his late master have so much misrepresented and calumniated.

Secondly, Those individuals, under the delusion which misleads them, have forgotten that books are the property of the public, and that, provided the meaning of the author be not perverted, every purchaser is entitled to animadvert upon their contents.

Thirdly, The same delusion has prevented their being aware, that when a medical author objects to any particular mode of practice, he does not necessarily censure the practitioner who had adopted or sanctioned it.

None of Dr. Hamilton's pupils ever heard him hint at a censure upon Sir Richard Croft for his treatment of the Princess Charlotte. Sir Richard, on that occasion, followed the rules he had been taught. Dr. Denman, his preceptor and father-in-law, had, in strong language, maintained that the first stage of labour should be allowed to continue for an unlimited time, and with this lesson regulating his conduct, Sir Richard did his duty faithfully, according to the best of his judgment. Although, therefore, no blame can be imputed to Sir Richard individually, it does not follow that a public teacher is bound to conceal from the notice of his pupils an explanation of the errors committed in the treatment of that interesting case.

Practically considered, all published cases should be regarded by a teacher and an author as illustrating his precepts, either as examples or as warnings; and provided the selection be appropriate, and the quotation faithful, there can be no ground for complaint. Dr. Murphy has not only dissented from this general proposition, but has expressed his displeasure at the same case having been repeatedly referred to, evidently from his not understanding that an individual case may illustrate as many precepts as there may have been errors committed in its treatment.

Under the delusion that Dr. Hamilton had reviewed and censured the practice of the Dublin Lying in Hospital, Dr. Murphy has reiterated the absurd charge, that Dr. Hamilton ought to have previously pub-

lished an account of the cases which had occurred in the Edinburgh General Lying-in Hospital; and this he has had the hardihood to do after Dr. Hamilton has **CONVICTED*** his late master of a deliberate falsification of the records of that hospital, by suppressing half of a sentence, and by interpolating certain words.

When the reader considers that Dr. Hamilton, in his "Practical Observations," has only incidentally referred to some of the cases which had occurred in the Dublin Lying-in Hospital, and has quoted only one of them, he will at once see the unfair advantage which has been taken of his Observations on Hospital Practice, notwithstanding his having protested against such a discussion, as having no relation to the object of his work. No professional man doubts that patients in the higher ranks require a different mode of treatment, both in diseases of the general system, and in the act of parturition and its consequences, from that which is adapted to those in the lower ranks.

With these preliminary remarks, Dr. Hamilton now proceeds, *firstly*, to lay before the reader a few specimens of the most flagrant misrepresentations with which he charges Dr. Murphy. *Secondly*, to shew that several of Dr. Murphy's incidental remarks are contrary to the established principles of midwifery; and, *thirdly*, to prove that Dr. Murphy, in the article referred to, has advocated modes of practice in cases of difficult and dangerous labours, which are of the most injurious tendency. If Dr. Hamilton make out these propositions to the satisfaction of the reader, he will feel himself exonerated from noticing any article which may in future appear under the signature of Dr. Murphy or his coadjutors.

I.—Specimens of Dr. Murphy's Misrepresentations.

Dr. Murphy,—trusting that his readers may not be aware, that while two practitioners agree in a general principle of practice in certain cases, they may propose different, and even opposite means for carrying the object of that principle into effect,—has taken much pains to identify Dr. Hamilton's directions for the management of the first stage of labour with those of Dr. Burns.

The deviation from the usual mode of practice in the management of the first stage of labour, which Dr. Hamilton claims to have introduced, is limiting the duration of that stage where there are regular labour pains to twelve or fourteen hours, and it is upon this principle that Dr. Burns and he are agreed. As Dr.

* Dublin Medical Journal, No. 41, p. 197.

Burns has expressed it, page 498, ninth edition,—“Dr. Hamilton makes it a rule to have the first stage of labour finished within a given time.”

But Dr. Murphy cannot fail to know (for indeed he has himself stated it), that while Dr. Burns advises dilating the os uteri, by insinuating the fingers and opening them, Dr. Hamilton's directions are, to support the os uteri during the pains, by pressure on its edge. It is, therefore, most unbecandid to allege identity of practice; and all Dr. Murphy's declamation upon this subject must necessarily fall to the ground.

In saying this, Dr. Hamilton gives no opinion on the propriety of Dr. Burns' practice, having never tried it, except in cases of hæmorrhage, &c. where the artificial opening of the os uteri became a matter of urgent necessity,

After having thus so unfairly confounded two different modes of practice, Dr. Murphy does not scruple to accuse Dr. Hamilton of ambiguity of language, an accusation which has at least the merit of novelty, and is to be especially noticed by and by.

In his review of the notice which Dr. Hamilton has been forced to take of the cases of laborious labours which had occurred in the Dublin Lying-in Hospital, Dr. M. has not only suppressed certain most essential facts of those cases*, but has also misrepresented Dr. Hamilton's remarks. It is, however, only necessary to give the following as examples of the whole:—

A case is much commented upon, page 426, Dublin Journal, No. 42, recorded in the Practical Treatise, page 465, No. 210, which Dr. H. admits that he has designated as a shockingly mismanaged one. Instead of quoting the authentic record of that case (as Dr. Hamilton had done), Dr. Murphy has given a most garbled and disingenuous report of it.

He says,—“She was of a most fretful and anxious disposition, and had been in labour from the 20th to the 23d of February. The action of the uterus throughout was very inefficient; there was no dilatation on the 20th. On the 21st, the os tincæ was dilated to the size of a crown; on the 22d, nearly the same; but

during that night, though the uterus continued to act imperfectly, it was nearly completed, excepting towards the pubes, where a portion still covered the head of the child (a fact which Dr. Hamilton seizes upon to attribute the delay to interception of the cervix); the pulse after this became hurried; breathing difficult, and great anxiety, with considerable debility. She was then given an opiate, in the hope that the uterine would act with more effect afterwards; rest was produced for some time, but when the pains returned, the same symptoms appeared in a more urgent form. The head was immediately lessened, and almost every bone removed, before it could be delivered; and even after it was brought down, much caution was required to free the shoulders and body. She expired almost immediately, for which no cause is assigned.”

Now Dr. Hamilton charges Dr. Murphy with having suppressed certain important facts of this case, which are necessary to render it intelligible, and also of having founded, upon the suppression of those facts, certain injurious accusations against him.

Firstly, Dr. Murphy says, that the woman had been in labour from the 20th till the 23d of February, whereas the record bears, that “*she was admitted on the 17th February, with the liquor amnii dribbling away,*” and that “*pains began on the 18th, and continued on the 19th.*”

Secondly, he has suppressed, that “*on the 20th the head of the child was found low in the pelvis, the edges of the os uteri thin and lax, the pains had returned in an urgent form,*” and that “*the woman had expressed herself as suffering the most acute distress.*”

Thirdly, in the authentic record, it is stated, that “*on the morning of the 23d the pelvis felt of sufficient size to allow the head to pass, and all that seemed wanting to effect this was, that the pains should become expulsive;*” a circumstance carefully concealed by Dr. Murphy.

Fourthly, the following report of the case at 9 P.M. of the 23d, is also suppressed by him,—“*On examination, the head was found in the same situation as in the morning; and had it not been that the mouth of the womb still remained over it next the pubes, an attempt would have been made to deliver with the forceps.*”

Fortified by the suppression of these important particulars, Dr. M. has had the extraordinary temerity to prefer the following accusations against Dr. Hamilton*:

Firstly, he says, page 430, “Dr. Ha-

* Thus *inter alia*, in page 425 (Dublin Journal, No. 42), in a reference made to case No. 150, Practical Treatise, page 464, Dr. Murphy has suppressed the most important fact, that the scalp of the infant was allowed to protrude through the external parts for nearly twelve hours.

Again, in the same page of the Journal, in alluding to case No. 509, page 470, he has concealed, that the bladder of the woman had been forced down before the head of the infant, and also that the woman had already had two still-born children.

* The accusations are not enumerated in the order in which they are made by Dr. Murphy, for it did not suit his mode of warfare to be regulated by the *lucidus ordo*.

milton gives this case as being of 96 hours' duration, though there was no dilatation of the os tincæ till the 21st, 60 hours before delivery." Even *he* durst not have made this allegation if he had not suppressed the two first facts above presented to the reader, as stated by Dr. Collins.

The second accusation is in the following words, page 429,—“ Dr. Hamilton asserts the cause of delay to be the interception of the cervix uteri, though at no period of the labour did the pains become expulsive, and throughout the uterus acted imperfectly; the head, therefore, could not have been forced down upon the pubes, so as to intercept the cervix. Dr. Hamilton has therefore assumed a condition of which there is no evidence.”

Really it is difficult to find terms which a gentleman would choose to employ in repelling this accusation. The suppressed facts, Nos. 2, 3, and 4, of the authentic record of the case, completely establish Dr. Hamilton's assertion, for the head of the infant is described as having been low in the pelvis, with the os uteri undilated on the 20th of February; and on the 23d, it is reported that the mouth of the womb still remained over it next the pubes.— Could any man but Dr. Murphy venture to assert, that the uterus was *not* interposed between the head of the infant and the bones of the pelvis?

Thirdly, Dr. Murphy says, page 431,—“ It might have puzzled those to whom Dr. Hamilton addresses himself, to explain how he could accomplish so much under so many difficulties as this case presented. To complete, in little more than two hours, a labour in which the pains were so weak as scarcely to produce any effect upon the os tincæ, and the utmost difficulty in extracting the child, even when the head was broken up, is a degree of skill which would require something more to make it intelligible than mere assertion.”

Had not Dr. Murphy deliberately concealed from his readers, that upon the morning of the 23d February, “ the pelvis felt of sufficient size to allow the head to pass; and that all that seemed wanting to effect this was, that the pains should become expulsive,” he could not have preferred this very modest insinuation. All that was necessary on the morning of the 23d, was to clear the head from the uterus, and to apply the forceps.

There are some incidental remarks hazarded upon this case by Dr. Murphy, to be noticed in illustration of the second proposition. It is only necessary, therefore, to add, that the explanation of this most melancholy case is abundantly simple, though it certainly did puzzle Dr. M.

and his late master. The liquor amnii was discharged on the 17th of February, and pains began on the 18th. The liquor amnii having been discharged, the uterus necessarily became in close contact with the person of the infant; and when, on the 20th of February, the child's head was found low in the pelvis, the uterus must have been interposed between it and the bones of the pelvis. This Dr. Hamilton has called intercepted, and he sees no reason to alter the expression. “ On the morning of the 23d the pelvis felt of sufficient size to allow the head to pass, and all that seemed wanting was, that the pains should become expulsive.” At this period, instead of using the forceps, which would have supplied the place of the pains, the poor woman was left to her fate. After this the pulse became hurried, with difficult breathing, &c., and an opiate was given, which had the effect of suspending the uterine action, while the pressure of the head of the infant for many hours, produced such swelling of the soft parts lining the pelvis, as to oppose a serious obstacle to the extraction of the infant. Of course, this swelling subsided after death, and could not be discovered by dissection; but that such is the only explanation of this case is indisputable, for there was no actual deficiency of space.

With the following statement, Dr. Hamilton concludes his evidence of Dr. Murphy's habitual misrepresentations:—

He says, page 422,—“ From the recoveries are omitted by Dr. Hamilton, Nos. 725, 1053, and 1041, also quoted for a different purpose by Dr. Hamilton, so that even this list of Dr. Hamilton's when corrected, gives only four deaths and 14 recoveries, where the infant had been some time dead before extraction.”

This paragraph relates to Dr. Hamilton's allegation, that, notwithstanding the high value attributed to the use of the stethoscope in the Practical Treatise, there are 19 cases where the sufferings of the poor women were allowed to continue for hours after the infant's death had been ascertained by that instrument; and of the 19 cases, that 8 of the women died, and 11 recovered. This assertion, so strongly denied by Dr. Murphy, Dr. Hamilton fearlessly repeats, and can find no difficulty in satisfying the reader.

In 6 of the 8 cases of death (of the women), viz.: No. 126, page 158; No. 32, page 300; No. 605, page 473; No. 665, page 478; No. 817, page 477; and No. 1091, page 483; it is distinctly stated, that the death of the infant had been ascertained by the stethoscope some hours previously. In a seventh case, No. 173, the words are, — “ the child was evidently dead;” and in the eighth case, No. 1038

the expression is,—“as the foetal heart had ceased to act,” &c. Can any one doubt that these are cases where the stethoscope had been applied?

Dr. Murphy has asserted, that from the recoveries are omitted Nos. 725, 1053, and and 1041. Throughout the whole of his article Dr. M. has drawn largely on the credulity and supposed ignorance or carelessness of his readers; but it is almost incredible, that he should have made an assertion, the verity of which, any one who has the Dublin Medical Journal for November, 1838, No. 41, could at once ascertain, by turning up page 196. The reader will find in that page, line 8, the case No. 725, and in the same page, line 13, the case 1041, enumerated among the recoveries. As to No. 1053, that could not be included, because it is expressly stated, page 482, Practical Treatise, “that the head was lessened *as soon as the child's death was ascertained.*” It could not, therefore, be cited as a case where the sufferings of the poor woman were allowed to proceed for hours after the stethoscope had indicated the death of the infant.

But not contented with this extraordinary imposition on the credulity of his readers, Dr. M. has deliberately accused Dr. Hamilton of having enumerated among the deaths two cases, No. 32, T, and No. 1091, U, which, in his former letter, were quoted to prove that the patients' lives were brought into great jeopardy, while the child, according to the evidence of the stethoscope, continued to live, and he refers (in the foot-note) to the Dublin Journal, No. 41.

No such cases are recorded in the Journal No. 41, but in No. 38 they are cited; and in page 223 of that No. of the Journal, it is specially stated (in reference to No. 32, page 300, Practical Treatise) that the woman was sent into the hospital in *severe labour, with a countenance expressive of great anxiety, pulse 120, the foetal heart acting with rapidity, and that after twelve hours' suffering, the action of the foetal heart having ceased to beat, she was delivered by the crotchet, and died in fourteen hours.* As to case 1091, the record bears, that the foetal heart was quite audible till eight hours previous to the birth. This woman died on the eleventh day.

If these be not cases where the poor women's sufferings were allowed to continue for hours after the death of the infant had been ascertained by the stethoscope, Dr. Hamilton certainly does not understand the English language. The same cases, as already stated, may be cited, as illustrating several practical precepts. There can be no doubt that the cases No. 32 and 1091 shew that the poor women's lives were brought into jeopardy before

the death of the infant, and there can be as little doubt that after the death of the infant had been ascertained, the unfortunate creatures were allowed to suffer unavailing pains for hours.

In actions at law, whether civil or criminal, witnesses sinning against the ninth commandment, which is universally admitted to be a transgression of a heinous character, incur the heaviest penalties. But the influence of their transgression in any civil or criminal action is limited to that individual case.

How different is it where the medical profession is concerned! A medical professor of an established University, after having been engaged in extensive practice for nearly half a century, had published the result of his experience for the information of his brethren, and for the benefit of the public. Two physicians who had held the respectable situations of master and assistant to the Dublin Lying-in Hospital have been proved to have deliberately misrepresented that work, by means of garbled extracts and other artifices. Many of the junior members of the profession may have been thus prevented from consulting the work in question, and hence the means of saving the lives, both of infants and of women, in certain cases of difficulty and danger, may remain unknown to them. But not contented with misrepresenting Dr. Hamilton's opinions and precepts, by which they prevent the junior members of the profession from consulting his works, they have, by fraud in language, endeavoured to hold out his precepts for the management of laborious labours, to those who may have chanced to have read them, as inculcating a “hasty, unnecessary, and consequently injurious interference, as meddling midwifery,” &c.

II.—Evidences of Dr. Murphy's Ignorance of the Principles of Midwifery.

On the first perusal of Dr. Murphy's paper, there were so many proofs of a deliberate intention to impose upon the credulity of the readers of the Dublin Journal, that it was Dr. Hamilton's impression that the incidental remarks betraying ignorance of the fundamental principles of midwifery, were simulated for the same purpose.

A careful review, however, of the practice adopted in the Dublin Lying-in Hospital, while Dr. Murphy was assistant, now enables Dr. Hamilton to understand that the incidental practical remarks alluded to are the conscientious opinions of that individual.

In page 43f, Dr. Murphy has the following words:—“Pressing on, or supporting the anterior edge of the os tincae would,

of necessity, act against the head, just in the same way as if two fingers were applied to the head itself, and the difference in both cases, where the uterus and not the fingers effect the dilatation, is so slight as to be immaterial; but when the practice is applied where there are no strong forcing pains, and the fingers are, as it were, to supply the place of the uterus, it in no way assists us in understanding how it is to be done."

This sentence seems to import that it is Dr. Murphy's opinion, that pressing with two fingers on the head of the infant during the labour pains has the same effect as pressing upon the anterior edge of the os uteri, he having evidently not understood that during labour the head of the infant is passive, and that the uterus is the active agent.

When the uterus is interposed between the head of the infant and the bones of the pelvis, the influence of the pains is prevented from extending to the os uteri. Supporting the edges of that part during the pain, counteracts this interruption, as every one who has adopted the practice well knows.

Again, in page 424, Dr. Murphy uses the following words:—"In order to make this objection intelligible, he (Dr. H.) asserts the cause of delay to be the interception of the cervix uteri, though at no period of the labour did the pains become expulsive, and throughout the uterus acted imperfectly; the head, therefore, could not have been forced down upon the pubes, so as to intercept the cervix."

From this sentence, it is evident that Dr. M. believes that the uterus cannot be interposed between the head of the infant and the bones of the pelvis, *without there having been expulsive uterine contractions.*

If he had not been taught, that occasionally, when the liquor amnii has been discharged before there be any dilatation of the os uteri, the infant's head, included in the uterus, sinks low into the pelvis, so as almost to fill the cavity, the record of the melancholy case, No. 210, might have opened his eyes to the fact. He has, indeed, endeavoured to conceal this from his readers, by suppressing sentences, No. 1 and No. 2, already referred to in the history of the case.

Dr. Murphy, in allusion to that most mismanaged case (No. 210, page 465), has the following observations:—"Dublin Journal, No. 42, page 429,—"Perhaps Dr. Hamilton will allow, that the only utility of opiates, in cases of protracted labour, is to suspend inefficient uterine contractions, which wear out the strength of the patient, without advancing the delivery, or to render these contractions more powerful, and there are no marks by which the

one result or the other may be calculated upon."

Here is an attempt to justify, upon Dr. H.'s own authority, the use of the opiate in that melancholy case. The reader will find, on referring to the 2d part of the *Practical Observations*, page 89, a very different rule for the exhibition of opiates.

Dr. Hamilton's words are—"The *safety* and the utility of opiates must be very carefully considered before being prescribed. If there be pain in the head, or any circumstance whatever which might render the further protraction of labour for ten or twelve hours injurious, opiates are most *dangerous*."

It is to be noted, that the woman had been in labour for several days, and that "the pulse had become hurried, breathing difficult, accompanied with great anxiety and considerable debility," before the opiate was administered.

Another evidence of the truth of the proposition under consideration is selected out of several which might be adduced.

In commenting upon a case where Dr. Hamilton applied the forceps, Dr. M. has the following expressions, page 433:—

"It must also strike the intelligent practitioner, that the forceps employed for an hour and a half, compressing such a head, would be a very likely way to produce such an effect (alluding to the infant having been born in a state of suspended animation, from which it was recovered); besides, it is not probable that the forceps could be applied without moving the head from its position; and still less, that some meconium would not have escaped if at all pushed back, had the child been previously in danger." By the above quotation, it appears that a person who had been assistant-physician to the Dublin Lying-in Hospital is ignorant of one of the rules for the use of the forceps, with which every tyro of the profession is familiar—viz., that during the interval of working, the pressure of the instrument upon the head of the infant is to be removed. Compression of the head of the infant, by means of the forceps, for an hour and a half, was never heard of in this part of the world.

As to the head being moved from its position by the application of the forceps, that is an effect of the application of the instrument totally unknown here. If, indeed, such forceps as those which had been employed in the Dublin Lying-in Hospital, during Dr. Murphy's attendance, had been used in the case alluded to, the introduction of the instrument would have occasioned much pain, and probably danger*; but even a bungling operator could

* In the *Practical Treatise*, page 12, it is stated, that the blades of the smallest sized forceps used

not have moved the head from its position; for the record bears (what is the real truth), that the head completely filled the pelvis.

Marvellous, indeed, are Dr. Murphy's remarks on the use of the forceps. He denies (*Medical Journal*, No. 42, page 442) that, by means of the forceps, the head of the infant can be safely diminished by approximating the parietal bones. He * asserts, that the pressure of the instrument must destroy the life of the infant, and must be dangerous to the parent; and he appeals to a grossly mismanaged case, that of Lady T.

In his abuse of Dr. Hamilton's precepts, he has very innocently let out the fact (page 443) that "Dr. Hamilton, in fifty years' practice, where he had charge of the patient from the beginning, only used the forceps 35 times—not once in the year." Will any other individual than Dr. Murphy or his late master venture to allege that this example is encouraging "junior practitioners to a hasty, unnecessary, and consequently dangerous interference?"

As Dr. Murphy has, relying on the carelessness of his readers, rung the changes upon the ambiguity of Dr. Hamilton's language, it is necessary to settle that question before proceeding farther.

By this accusation, he probably expected to withdraw his reader's attention from the frauds of his own language, and that of his late master. He has, indeed, not attempted to vindicate his master's garbled extracts, substitution of words, &c., but he has improved upon his plan, by boldly suppressing facts, and preferring groundless charges. This may be the effect of the delusion under which he labours; but it is absolutely necessary that it should be brought under the particular notice of the professional reader.

Language may be ambiguous to the reader or to the hearer, in consequence of his own ignorance. A discussion upon the principles which regulate rent, though expressed in the most appropriate language, would be totally unintelligible to a person who had not studied that intricate question; and the same observation is applicable to various scientific subjects, such as astronomy, navigation, &c. Dr. Hamilton addressed his practical observa-

tions to the profession; and it must be perfectly evident, that if the readers of his work are ignorant of the elements of midwifery, his language may appear to them to be ambiguous.

A person who believes that pressing with two fingers on the head of the infant, during the first stage of labour, is tantamount to pressing on the edges of the os uteri; that the interception of the cervix uteri between the head of the infant and the bones of the pelvis cannot take place without the previous occurrence of forcing pains; that the application of the forceps in cases where the head is wedged in the pelvis must necessarily move the head of the infant from its position; that the forceps cannot safely lessen the head by approximating the parietal bones; and that the use of that instrument by a person who has been taught the rules, and who employs forceps of a proper construction, must necessarily occasion danger both to the infant and to the mother; cannot be expected to understand the practical precepts of an experienced practitioner, however clearly expressed, and however intelligible they may be to those who have been properly educated.

III.—*Proofs of the dangerous Tendency of the Modes of Practice in laborious Labours, advocated by Dr. Murphy and his late Master.*

Before proceeding to the consideration of the third proposition which Dr. Hamilton has undertaken to prove, viz., that certain modes of practice in cases of laborious labours, advocated by Dr. Murphy, in the article referred to, are of a most dangerous tendency, it is necessary to notice Dr. Murphy's remarks on the records of the cases which had occurred in the Dublin Lying-in Hospital during his incumbency, as published by his late master.

He begins by saying, page 423, that "Dr. Hamilton may have supposed, that because the cases he has been pleased to select are not incorrectly quoted, there can be no cause of complaint; but in some of them he has obviously misunderstood the details. The omission of the disproportion in one case (O) * we have seen,

* Dr. Hamilton finds that he has quoted two cases under the letter O, but he presumes that the case alluded to by Dr. Murphy is recorded in page 473, No. 665, of the *Practical Treatise*; and a transcript of that record will shew the manner in which Dr. Murphy chooses to misrepresent, on every occasion, the cases referred to by Dr. Hamilton.

"Was 35 hours in labour of her first child, for the last 24 of which the head had not made the least progress. Her strength being exhausted, and the child some hours dead, as ascertained by the stethoscope, delivery was effected by lessening the head.

"She continued to recover favourably till the fourth day after delivery, when she was suddenly

in Britain, even when completely closed, measure from three and one-eighth to three and a half inches.

* He refers to the authority of Baudelocque in confirmation of his allegation, that the head cannot be safely diminished by the forceps, forgetting that each blade of Baudelocque's forceps is nearly a quarter of an inch in thickness. He might have known that Madame la Chapelle, even with the French forceps, repeatedly succeeded in bringing a living infant through a defective pelvis.

is enough to furnish Dr. Hamilton with an argument. Similar instances occur in other cases; for instance, where the treatment is not mentioned, he assumes it not being adopted (C. D.), though Dr. Collins quite sufficiently explains what the general treatment was; nay, on the very strength of the omission, Dr. Hamilton endeavours to make the practice contradict the precept."

Again, he says: "When the number of cases Dr. Collins has brought forward is considered, the necessity for brevity in each, and that most of them are considerably curtailed, in order to state the particulars in as condensed a form as practicable, some errors in sense might be pardoned; and if they appeared to be treated in opposition to the practice stated in the text, the fact of their being thus curtailed would be a sufficient reason to raise a doubt as to their accuracy; but when, without there being any positive errors, it appears that the omissions in one case (O)—an ambiguity in another (I)—the misconception of a third (K)—form the ground-work of Dr. Hamilton's commentaries, it only shews how completely his zeal in defence of his opinions has obscured from him the most palpable mistakes in the evidence he has adduced in their support."

Much as Dr. Hamilton has had occasion, in his professorial capacity, to point out the inaccuracy of reasoning of medical authors, he fairly owns that he has seldom met with any thing like the remarks in the foregoing quotation.

Firstly, it is asserted that quoting cases correctly does not exclude complaint on the part of the author.

Secondly, that some errors of sense, if in opposition to the practice stated in the text, should raise a doubt as to the accuracy of the details of the cases.

Thirdly, that the omission in one case, and the ambiguity in another, and the misconception in a third, being most palpable mistakes, should have been understood and corrected by Dr. Hamilton.

attacked with the most acute pain in the abdomen, which resisted the most active treatment, and she died in 48 hours.

"On dissection, a large quantity of a deep straw-coloured fluid was found in the abdominal cavity, and all the viscera were extremely vascular. The uterus was soft, but in other respects healthy. The vagina was in a sloughing state."

It is impossible to imagine a more disingenuous allegation than that of Dr. Murphy, in asserting that there had been a disproportion in this case, which had been omitted. If there had really been a disproportion, it was unjustifiable to allow the infant's head to make no progress for the last 24 hours; and the fact of the sloughing of the vagina is a proof that the continued pressure of the infant's head upon the parts lining the pelvis had been not only injurious, but fatal.

Hitherto Dr. Hamilton, in common with the rest of his professional brethren, has given credit to Dr. Collins for the candour and fidelity of his details, and has believed his assertion, page 86 of the *Practical Treatise*, that on studying the records of the Dublin Lying-in Hospital, "the reader will be thus enabled to form his own conclusions, both as to the practice adopted in each case, and as to the general result."

If the particulars of each case have not been accurately detailed, how is it possible for a reader to understand the practice adopted? If there be errors of sense, omissions and ambiguity in language, of what value can the recorded cases be? Dr. Murphy says, that "in one case, although bleeding is not mentioned in the treatment, that is no evidence that the patient was not bled;" and in another case, that "although, in describing the appearances on dissection, there is no mention of deficiency of space in the pelvis, it is not fair to conclude that there was no such deficiency."

The accusation which Dr. Hamilton prefers against Dr. Murphy and his former master, is, that they have not quoted fairly his *Practical Observations*, and they now retort upon him, that he has quoted accurately the cases published in the *Practical Treatise*, but that he should have corrected the sense—that he should have supplied the omissions, and should have cleared the ambiguity of the records; presuming, as a matter of course, that Dr. Hamilton, being a native Caledonian, must have the second sight—a surmise against which he takes the liberty to enter his very solemn protest.

It is only necessary to add, that much as Dr. Hamilton has to complain of the conduct of Dr. Collins, he must have better evidence than such a witness as Dr. Murphy has proved himself to be, before he can question the accuracy of the published cases of the Dublin Lying-in Hospital. They bear internal evidence of candour and fidelity.

For the management of laborious labours, the *Practical Precepts* which Dr. Hamilton's experience has led him to adopt and to recommend, are, that it is in the power of the practitioner to foresee and to prevent the occurrence of injury to the infant or to the mother; that when the infant's head comes within reach of the forceps, that instrument should be had recourse to before there be any risk of injury either to the mother or to the infant; and that, when called to a case of protracted labour, which had been mismanaged, the forceps or the crotchet must be employed, in reference chiefly to the state of the mother.

These precepts are stigmatized by Dr.

Murphy, as inculcating meddlesome midwifery, and by his late master, as cruelly encouraging the destruction of the child.

Very different are their precepts (supported by their practice in the Dublin Lying-in Hospital), for they declare, that "artificial assistance during labour should never be given till symptoms of danger take place; that in laborious labours, the death of the child always precedes any symptoms of danger on the part of the mother, and that, under no circumstances is it justifiable to destroy a living infant, until the state of the mother absolutely require interference."

The first of these propositions (Dublin Journal of Medical Science, for March 1837) is expressly stated in allusion to the cases which had occurred in the Dublin Lying-in Hospital (p. 43). The words are, "Nor was artificial assistance ever attempted till the safety of the patient absolutely required it."

This explains the appalling fact, that in 16,414 women delivered in that hospital during seven years, while in laborious labours, the forceps were only employed 24 times, the perforator and crotchet (or, as Dr. Murphy chooses to call it, excerebration) were had recourse to 79 times, it being admitted, at the same time, that the greatest degree of deficiency of space ever witnessed, was found to be $2\frac{1}{2}$ inches between pubes and sacrum.—(*Ibid* Practical Treatise, pages 15, 22, and 302.)

But this is not all; every sixth woman on whom the forceps was used, and every fourth woman on whom the perforator and crotchet were had recourse to, died; 8 out of the 24 infants, or 1 in 3, extracted by the forceps, were still-born. Thus, in 103 cases of laborious labour (of the second or third orders), 24 women and 87 infants were lost; making 111 deaths in those cases of protracted labour.

Dr. Hamilton's conviction is, that during the last half century, there have not been fifty crotchet cases in Edinburgh and its vicinity, making a population of at least 120,000; and he founds this opinion upon the fact of his having been very generally consulted upon all such cases of difficulty. Yet Dr. Murphy and his late master boast of the successful result of the practice in the Dublin Lying-in Hospital.

Assuming, then, that Dr. Murphy vindicates this precept, Dr. Hamilton finds it impossible to use too strong language in reprobation of it. The common sense of mankind has led to the universal belief that it is as much the duty of medical practitioners to prevent as to cure diseases. *Venienti occurrere morbo*, is a maxim adopted by all civilized nations.

If this principle be applicable to the

treatment of ordinary diseases, it must certainly appear not a little wonderful that it should be declared by Dr. M. and his late master to be inapplicable to the management of women in labour. Would any sane man employ a regularly educated medical practitioner to take charge of his wife when in labour, if he were not impressed with the belief that that practitioner could foresee and prevent the occurrence of circumstances endangering the health or life of the mother or child? Would he not, were he assured that no artificial assistance were ever to be had recourse to till symptoms of danger on the part of the mother should become manifest, hold it to be a wise measure to recur to the ancient practice of putting his wife under the care of an old woman, with directions to send for medical assistance "as soon as the safety of the patient absolutely required it?"

The second practical precept of Dr. Murphy is, that in laborious labours the death of the child always precedes any dangerous symptoms on the part of the mother.

He says (p. 420), "It has been PROVED, as Dr. Collins observes, that when the patient has been properly treated from the commencement of her labour, the death of the child takes place in laborious and difficult labours before the symptoms become so alarming as to cause any experienced physician to lessen the head."

Words can scarcely express the feelings suggested by the above remarks. It is here asserted that it has been PROVED, that where a woman had been properly treated, the death of the infant always takes place before symptoms of danger occur; yet Dr. Collins has recorded, page 158, No. 126, that a woman was 59 hours in labour of her first child; that for the last 24 hours the uterus acted with tolerable regularity, the pains being at times strong, causing the head to press with much force against the ischia, where it remained stationary for the greater part of that time; that her pulse was very much increased in frequency, and that the external parts were œdematous before the proper assistance was given, while he admits, at the same time, that the action of the fetal heart had been distinctly audible in the right iliac region six hours before delivery; and when it is added, that after death the vagina was found in a state of slough, &c. can it be doubted that symptoms of danger must have taken place long before the fetal heart had ceased to act?

In the case (p. 473, No. 665) already quoted in the foot-note of p. 43, it is impossible to believe that the effusion into the abdomen, and the sloughing of the

vagina, had suddenly taken place after the death of the infant, for it is quite evident that the pressure of the child's head for twenty-four hours had occasioned inflammation of all the parts lining the pelvis.

One other case will be sufficient to convince the reader of the fallacy of this dogma of Dr. Murphy and his late master.

"The woman was 56 hours in labour; uterine action, until within six hours of the expulsion of the child, was extremely feeble, with long intervals. The head remained high in the pelvis, and although the ear could not be reached, it was evident the head had sufficient room to pass. The foetal heart was quite audible till within eight hours of her delivery. She died on the eleventh day.

"On dissection, the only morbid appearances found were in the bladder and vagina. In the bladder the mucous surface was covered with yellow lymph, and it contained a quantity of muco-purulent fluid. In the vagina opposite the right ischium, a portion appeared to have been destroyed by slough, but its texture did not in other parts seem materially injured, although of a darker colour than natural."

It must be obvious that in this case much injury had occurred before the death of the infant.

On the whole, the proposition under consideration is not only untenable, and is contradicted by the records of the Dublin Lying-in Hospital, but is of a most mischievous tendency, as it is calculated to lull young practitioners into a delusive confidence in the safety of their patient.

Dangerous as the preceding precepts are, the third proposition advocated by Dr. Murphy, while it is equally calculated to mislead the junior members of the profession, is so preposterous, that if Dr. Murphy's own words could not be brought forward to prove it, no individual who had been taught the elements of midwifery (by a competent teacher) could have supposed that any man who had ever seen practice could have hazarded it.

Dr. Murphy, in page 419, Dublin Medical Journal, says, "No practitioner is justified in destroying a living infant, without his having sufficient evidence to prove it actually necessary; as that necessity must arise from actual danger to the mother, so the evidence must be positive, not imaginary; or, in other words, *it must depend upon the presence of dangerous symptoms to the mother, not upon the conviction that they would have presented themselves, had not the child been destroyed.*"

Before it was possible for Dr. Murphy to have written this sentence, he must have obliterated from his mind all cases of deficiency of space, and all mechanical causes

which occasionally render it impossible to extract an entire infant through the natural passages. He must also have presumed that his readers must have been equally under the influence of the waters of Lethe.

Reasoning with such a person would be a hopeless task, and therefore Dr. H. presents the reader with the following recorded case, as completely shewing the effect of adopting the precept under consideration:—

P. 301, Practical Treatise, No. 3, the patient "was admitted, Sept. 2, at 9 P.M., in labour of her first child. The person in attendance, on making an examination, found an extremity low down in the vagina, which was thought to be the knee. She remained till three o'clock next morning quite free from pain, when the uterus began to act briskly, and, on repeating the examination, the elbow was discovered presenting. The body was now so closely wedged in the pelvis that it was impossible to turn with safety. The thorax was accordingly perforated, and the breach brought down with *immense difficulty*, owing to the extreme deformity of the pelvis. It required most laborious exertion, *for two hours and a half*, to complete the delivery, which was only accomplished by taking the child in pieces. She died in four hours."

On dissection, there was observed a considerable laceration between the cervix uteri and vagina to the right side.

"The pelvis, which was preserved, measured only $2\frac{1}{2}$ inches from pubes to sacrum. This was by much the most defective pelvis I ever met with in the hospital."

This record does the highest credit to the candour of Dr. Collins, and completely refutes the injurious insinuations of Dr. Murphy, p. 423, No. 42, Dublin Medical Journal, already noticed.

Indeed it would have been impossible to have fabricated a case more strikingly illustrative of the dangerous tendency of the three practical precepts advocated and acted upon by Dr. M. and his late master. Thus six hours were allowed to elapse after it had been ascertained that the labour was preternatural, before any assistance was offered, during which time the uterine action was suspended, and of course the operation of turning might have been safely performed. Not that the infant could have been saved, but that after the feet had been brought down, its head might have been opened, and the poor woman's life might have been preserved.

Instead of this, no assistance was offered till the body of the infant was so closely wedged in the pelvis that it was impossible to turn with safety, and then, after a

most laborious exertion, continued for two hours and a half, delivery was completed by taking the child in pieces, in the progress of which the uterus was burst. One that has not been in practice cannot depict to himself the dreadful tortures to which this poor creature must have been subjected, and yet she had repaired to an hospital munificently endowed, where she had a title to expect every possible attention.

As a general rule, governors of institutions for the treatment of diseases, ought to interfere as little as possible with the duties of the medical attendants; but when such dangerous principles of practice as those avowed by Dr. M. and his late master have been acted upon, and have been followed by such fatal results, it is high time for the governors of the Dublin Lying-in Hospital to inquire into this most important subject.

LECTURES

ON THE

CHEMICAL HISTORY, PATHOLOGY, AND
MEDICAL TREATMENT

OF

CALCULUS,

AND THE VARIOUS DISORDERS OF THE

URINARY SYSTEM.

By DR. VENABLES.

Diuresis saccharina.—This form of disease, usually known as the *diabetes mellitus* of authors, is perhaps as formidable, so far as health is concerned, as any in the whole catalogue of human maladies. It has hitherto resisted every plan of treatment, and, when once established, has invariably proved fatal. It is true that instances of cure are recorded, but these are readily explicable upon the fact that the real nature of the case has not been sufficiently understood. Authors have included, under the generic term *diabetes*, two species—the *diabetes insipidus* and the *diabetes mellitus*. The former, it is more than probable, has been frequently misunderstood, and confounded with diseases of a very different and comparatively innocent character. We have already noticed that an increased flow of urine may arise from a great variety of causes, transient in their nature, and no way injurious in their effects. But when the diuresis is either of the character described in the last lecture, or partakes of that which we are now about to describe, the disease is much more dangerous, and requires prompt attention.

The functional symptoms are few, and, indeed, sufficiently characteristic, at least so far as to put us on our guard and excite

us to a more close and minute investigation. Cullen defines diabetes—"Urinæ plerumque præternaturalis, copia immodica, profusio chronica." The mellitic—"Diabetes cum urina odoris, coloris, et saporis mellei." The insipid—"Diabetes cum urina limpida non dulci." If we meet with a patient complaining of voracious appetite, insatiable thirst, a dry or viscid mucus adhering to the lips and angles of the mouth, a harsh and dry state of skin, with emaciation, we may fairly suspect the presence of this disease in some form or other. When to these we add an excessive discharge of urine, and especially of a sweetish taste, we can have no doubt of the nature of the complaint. The disease is usually attended with considerable languor, and disinclination to every sort of exertion; affections of the stomach, such as great uneasiness and distress after meals; the mouth parched; the tongue white and foul, sometimes preternaturally clean and red, such as indicates great gastric irritation; pain and weakness of the loins. Aretæus tells us that the intestines feel as if burning—Τὰ σπλάγχνα καίεσθαι δοκεῖν; and he says that neither shame nor any other consideration can restrain them from voiding the urine. But if, he continues, they should retain the urine for a little time, the loins, testicles, and hips swell, but on voiding the urine the swellings immediately subside.

There is also very frequently a considerable sense of irritation and uneasiness, sometimes even of inflammation, about the urethra, especially the external orifice; anaphrodisia; a sense of chilliness of the feet and surface; œdema of the extremities; flatulence, with acid eructations; eyes dull and painful; colic†; vertigo;

* Nosologi Method., vol. ii. p.p. 243, 244, 245.

† Οὐ γὰρ διαλείπουν οὐρέοντες ἀλλὰ ὅπως περ ἐξ ἀφένιος ὀχετῶν ἀπανστος, ἡ φορῇ.
—De Caus. et Sig. Morb. intur, lib. ii. cap. 2.

cephalæa; gums spongy, frequently ulcerated. The respiration difficult, on even slight exertion; a sense of weight at the præcordia, and tenderness upon pressure; sighing, spirits exhausted, and the mind weak and peevish. The bowels unusually costive.

As the disease advances, a number of complications ensue, and other organs and functions become involved. Hence dropsies and pulmonic affections supervene, and speedily put an end to the miseries of the patient.

With the symptoms above enumerated, we find the urine voided in extraordinary and most unaccountable quantity. The diuresis is excessive, and the calls so frequent and so urgent that the patient is almost incessantly passing water. The quantity passed in a given time, has, in some instances, amounted to thirty pints in the twenty four hours; and this has continued for weeks, and even months. The urine, it has been remarked, greatly exceeds the whole of the ingesta, and Aretæus states that the urine even greatly exceeds the drink.

The urine varies in appearance; sometimes it is of a pale straw colour, sometimes it has a sort of bluish greenish cast, and sometimes it approaches to an opalescent appearance. One, however, of the most important sensible characters is its sweetness. This sweetness, however, may in some cases alternate with a bitter taste; as I shall have occasion to notice presently. Such is a summary of the leading symptoms of this dreadful affliction.

Causes. — With respect to the causes, they are involved in considerable obscurity. Aretæus observes that any acute disease may be the cause of diabetes, if terminating with a crisis it should leave behind it latent in the body any thing malignant which will ultimately terminate in diabetes. "Nor is it incredible (he says) that some of those poisons which affect the bladder and kidneys may become the cause of this disease*." However, it seems questionable how far other diseases of the above character act in inducing true diabetes. Fevers are the most likely of all acute diseases to bring on diseases of the urinary system, and such may readily be often confounded with diabetes. Sydenham, in his letter to Dr. Brady, in reference to the epidemics which prevailed in 1675 and 1680, says, that they were sometimes followed by diabetes, especially when an improper mode of treatment had been adopted. "Nonnunquam accidit," he says, "etsi perquam raro, ut senes, qui diu hoc morbo antea laborarunt,

ac interea venæsectionibus et catharticis imperite fuerint mulcati, in diabetem incidant, etiam febre jam perfecte fugata*." Fevers, we know, especially the more acute forms, are attended with a diminution of the urinary discharge; but as the fever advances, pale-coloured urine is frequently voided in considerable quantity, and which frequently continues after all the febrile action has subsided, and appears to be the consequence of nervous debility, and very different, indeed, in its character from true diabetes.

Of febrile affections, none seem to affect the urinary functions more powerfully than the exanthemata; and of these scarlatina, measles, and to which we may add, erysipelas, appear to have the most tendency of this sort. Indeed, I have already shewn you how frequently the urine is loaded with albuminous matter in scarlatina; and it is not improbable that a tendency to a diabetic condition, or this diathesis even, may be generated during these fevers. Sydenham, however, has left us no record from which we can judge of the nature of the disease which he has termed diabetes; for he gives no particulars, nor does he even mention the quantity or any of the qualities of the urine, "Etenim," he says, "cum sanguis eorum abhinc debilitatus assimilandis succis ei illatis prorsus impar reddatur, iidem per vias urinarias crudi adhuc et incocti exitum sibi querunt, proindeque præ ingenti urinæ copia, quoties eam reddunt, excretâ sensim vires labefactantur, et quasi substantia corporis per hanc elocacim exanantur†."

Exposure to cold, it has been said, sometimes excites diabetes; and Dr. Marsh mentions a case of confirmed diabetes in which the origin of the affection was distinctly traced to exposure to cold during a storm at sea, in which the loss of the vessel was momentarily anticipated. "This patient was four days at sea, and during the greater part of the time was to his knees in water; he was chilled with cold, and for the last two days there was not any supply of provisions. After quitting the vessel he felt himself constantly chilly, and could not by any means (to use his own expression) get warmth into him. Before this time he conceived himself in perfect health, but immediately afterwards decided symptoms of the affection in question manifested themselves‡."

It seems rather doubtful that mere exposure to cold, even under the most aggravated circumstances, could induce a true diabetes, that is, a saccharine condition

* Epist. 1, Responsor. Op. Th. Sydenh. p. 387.

* Ibid.

of the urine with diuresis. Dr. Prout, in commenting upon this case, urges the fact, that "Dr. Marsh had at the same time under his care, in the hospital, another man who had sailed in the same vessel, and was exposed to the same circumstances as the one who had diabetes. He, in like manner, for some time afterwards felt cold and chilly; but the disease with which he was attacked was not diabetes, but intermittent fever, to which it seems he had a predisposition*." In commenting upon this statement, Dr. Prout notices the difficulty of allowing cold to have been the cause of the diabetes in this case, especially when he alone of all the passengers, who no doubt must have been similarly exposed, was affected with diabetes; and this difficulty can only be explained by the supposition that he must have been either actually labouring under the disease at the time of the exposure, in consequence of which the symptoms were merely aggravated, or he must have had a strong hereditary predisposition.

An hereditary disposition to this disease seems to have been well established. Dr. Prout witnessed four instances of this hereditary disposition. I know of three instances in which the parents laboured under diabetes; and on examining the urine of some of the children an excess of urea was always indicated on the addition of nitric acid. Dr. Prout's cases are very interesting confirmations of the existence of an hereditary disposition to this affection. The first was that of a young gentleman, whose mother and uncle had died of the disease, and apprehensive that he himself suffered from the same complaint, Dr. P. examined the urine, and found no saccharine matter, but a considerable excess of urea; and further, two individuals of the same family, a brother and sister, died of the disease. Another, a lady, about 50, had either a brother or sister who died of it; and in the third instance a young girl, about 10 years old, who died of it; the father had died two or three years previously. The fourth was that of a gentleman, aged 54, whose father was said to have suffered from diabetes for many years before his death; and it is a singular circumstance that the former's son, aged about 30, complained much of being troubled with lithic acid gravel.

I have myself met with a case very lately, in which I was applied to, in consequence of an incontinence of urine, as it was represented. It was that of a boy about 11 years of age, who was in the habit of constantly wetting the bed, inasmuch that neither entreaties, threats,

nor even severe punishment, as it was stated, had been sufficient to break him of his filthy propensities. I examined several specimens of this boy's urine; it was of a pale reddish colour, somewhat like ale; smell aromatic; taste bitter and saline; specific gravity, 1026·37; and on adding nitric acid, crystallization, with an abundant crop of urea, in the course of from five to ten minutes. On inquiry, I learned that the father died of consumption, previously to the appearance of which he had been subject to frequent urinary affections, stated to be gravel; but that the great-grandfather had died of diabetes. Some instances of a somewhat similar description have occurred, and they seem to leave no doubt that a predisposition exists, and that this is often of an hereditary character. You will often, perhaps, in the course of your practice, be called upon in reference to the cases of children, especially at school, supposed addicted to the filthy practice of wetting their beds; but always look upon such cases with suspicion. The properties of the urine will often solve the difficulty; and it will always prove satisfactory, even to the complainers, to discover "that the poor child has not been so much to blame." Now, in such cases, always inquire whether this habit be confined to the time when the sufferer is in bed, or whether it occurs in their waking and conscious moments; for this seldom takes place under ordinary circumstances, at least when the patient is awake and conscious.

Among the causes, also, may be enumerated intemperance, and the immoderate use of spirits; excessive evacuations of every description; severe labour; poor, scanty, and acedent diet; injuries of the spine, and of the system of nerves arising from the cord. In such cases various exciting causes may act, by calling the morbid disposition into activity.

Aræteus mentions a curious cause, namely, the bite of a serpent, named *dipsas**. He states this to be a reptile, and that whomsoever it bites, is afterwards seized with insatiable thirst, and other symptoms of the character of diabetes. However, his description is not very perfectly that of diabetes, and it is probable that the irritation excited inflammation and fever, and that the indulgence in drink consequent upon it produced a diuresis.

Diagnosis.—We have already stated that many cases occur in which a flow of urine in excessive quantity takes place, and that

* On the Urinary Organs, p. 68.

* Ἀτὰρ εἰ ἐδάκῃ τις ὑπὸ τῆς Διψίδος τοῖνδε τοῦ ἑλκεος ἐπαθῇ.

such cases are very different in their symptoms and consequences from diabetes. This propensity to characterize an excess of the urinary discharge as diabetes, has led to numerous errors, and to great disappointments. It has been proposed by Dr. Prout to limit the term diabetes exclusively to a saccharine condition; and instances of this condition are occasionally met with in which there is no increase in the quantity of urine, but, on the contrary, it even falls short of the natural proportion. Dr. Prout, indeed, first suggested the probability of such cases; he says, "In endeavouring to explain the affections accompanying diabetes, we must consider the disease in a twofold light; first, as a simple saccharine condition of the urine, without any regard to its quantity; and, secondly, as a similar condition of the urine, accompanied by more or less of *diuresis*."

"With respect to the first of the above forms of disease, no one seems hitherto to have distinctly described it; its existence, therefore, at least as an original form of disease, must, in the present state of our knowledge, be considered as somewhat hypothetical. That such a form of the disease, however, can exist, seems to be proved by the fact, that diabetes may be so far cured as to be literally reduced to the state in question; that is to say, the quantity of urine may be rendered natural, and all the usual symptoms of the disease be much relieved, and *yet the urine remain saccharine*. Now if a common case of diabetes can be reduced to this state, there seems to be no reason why the disease may not originally exist, for some time at least, in a similar form*." In confirmation of these views, Dr. Prout states that he saw a case in which the symptoms of diabetes in the worst form had supervened, in which, long previously, the patient's attention had been excited by the qualities of the urine, before its quantity became remarkable. In this case it was observed that, wherever the urine happened to fall on the dress, an imperfect crystallization took place, and the part became stiff and clammy, and attracted the dust.

It occurred to me to meet with two cases in Essex — one of which, at my request, consulted Dr. Prout — of very nearly the complexion mentioned by Dr. Prout; and both occurred very nearly at the same time. The first case was that of a married woman, about two or three and forty years of age, who applied to me on the 7th May, 1829. This lady, when young,

was a very slender and delicate-looking girl, but when I saw her she had grown now very lusty, and to all appearance seemed in excellent health. She has, however, complained at various times, but within the last two years has felt a great deal worse. She attributes the origin of her disease to a confinement, about twenty-four years since, when she had a very bad labour.

At present she complains of pains in the loins and region of the kidneys, extending along the course of the ureters to the bladder. The left side was swollen, from the ribs down to the ilium and pubes. There was great irritation and pain in passing water, with pain in the genitals; great difficulty in retaining the urine when any call to pass it arose; on coughing it passed involuntarily. Tongue dry and sulcated, not particularly red; skin dry, harsh, and feverish; thirst; bowels costive; appetite good; catamenia regular; occasional headache; cough but slight; no expectoration; nervousness.

I had two specimens of this lady's urine, the one passed before breakfast, the other after dinner. The colour pale straw, or inclining to green; the smell of the morning not sensibly sweet; that passed after dinner had somewhat of the sweetish smell of newly-mown hay. Taste of the morning urine not sensibly sweet; that passed after dinner had something of it. Now in this case there was evidently nothing in the general symptoms that would have led even to the suspicion of a diabetic condition of the urine, and consequently this case might have run on, if neglected, till severe diuresis with emaciation; and the symptoms previously mentioned unequivocally pointed out the nature of the complaint.

On the 9th May, in the year 1829, just two days after the above, the following case occurred:—J. P—r, a merchant dealing largely in wine, &c., and farming a large property of his own, applied to me complaining of symptoms of indigestion. This gentleman was of a full habit, very lusty and corpulent, and in no way of an emaciated appearance; of a florid complexion; and any thing but the appearance of bad health. Nothing certain or precise could be ascertained relative to prevailing family diseases. His mother or grandmother died with pulmonic symptoms, which were considered of a consumptive character; and a niece of his was affected with an abscess in the loins, but of what precise character or description I could not discover.

He consulted me once before in a casual sort of way, but without entering into the

history of his case. On the present occasion he complained of a puffy swelling of the right knee, but which was not painful. He complained, however, of pains generally through all the limbs, and was considered labouring under rheumatic gout, to which, although much addicted to field sports, especially shooting, he was very subject. He complained greatly of fever, as he termed it, in his stomach; the lips dry and parched; tongue dry, coated with fur, sulcated; saliva viscid, and concreting in the angles of the mouth; thirst urgent; appetite good, but not voracious; no emaciation; bowels regular; pulse 96; respiration free, regular, and equal; the urine natural in quantity; nor did he feel any uneasiness nor any irregularity in the functions of the urinary system. In this case, therefore, it is evident that there was nothing which could lead to any suspicion of the state of the urinary system.

At my request, however, upon this occasion at my house, he passed about half a pint of urine, which was of a yellowish green colour, the specific gravity of which, by the ouro-barometer, was 1.035. From the high specific gravity, I pronounced the great probability of the saccharine state of this fluid; and, on trial, my prognosis was verified, for it was distinctly sweetish to the taste; and by the treatment described in a former part of these lectures, sugar was readily obtained, and in tolerably large quantity.

The specific gravity of the urine in the case previously mentioned was found, on examination, to be—of that passed in the morning, 1.029.5; of that passed in the afternoon, 1.037. It was distinctly saccharine, contained but little saline matter, and but very slight traces of urea. On the 9th, I had two other specimens—one, passed the day before, was of a pale colour, and somewhat opalescent, and a slight tint of green, smell peculiar, and what I occasionally name “diabetic;” it had no remarkable taste, but appeared to contain some oily or fatty-looking matter; the specific gravity 1.026; reddened litmus paper, and contained a considerable excess of urea; and there was also a very small quantity of a reddish looking crystallized matter fell to the bottom of the vessel in which the urine stood, and which, on examination, proved to be principally lithic acid.

The second specimen, passed on the 9th, in the morning, by the same patient, was clear, and almost like spring water; could just be said to have a greenish tint; and, after standing at rest for some time, a slightly buoyant mucous cloud gradually subsided; the surface presented a greasy

appearance, owing to a fatter sort of film floating upon it. This specimen was devoid of taste and smell; specific gravity 1.012, and faintly reddened litmus paper. Urea present, but not in absolute excess.

On the 10th May, as before, I obtained three specimens of urine from Mr. P—r. The first, passed in the night, had a specific gravity of 1.035; the second, early in the morning, had a gravity equal to 1.0367; and the third, passed after dinner the same day, had a specific gravity of 1.040. All three were of a pale straw colour, perfectly transparent, and free from cloud or mucus; were distinctly sweetish to the taste; and contained a proportion of fatty or oily matter.

On the 12th, three specimens, which all presented the same general characters: one, passed the night before, sp. gr. 1.041, reddened litmus, and contained sugar; that passed the morning previous had a sp. gr. = 1.040, and lithate of ammonia separated in small quantity—it was sweetish; that passed on the morning of the 12th presented the same sensible characters—sp. gr. 1.035; urea separated from this specimen in abundance; on the addition of nitric acid, in an hour became an almost solid crystalline mass. This gentleman was put upon treatment which I shall describe to you in its proper place; my object at present is merely to point out the variations which occur in connexion with alterations in the specific gravity. Thus it was frequently found that the specific gravity of the urine varied; sometimes high—above 1.035—and then the sugar predominated, and urea in proportion disappeared, although never wholly absent. Again, the specific gravity diminished, approaching 1.030, when the urea predominated and became abundant, and in proportion the sugar disappeared. As I had an opportunity of examining the urine in this case very frequently, perhaps it may prove of advantage to present a sort of tabular view of the specific gravity upon the several occasions, with the general properties of the urine in connexion with each, so that we may be able to perceive at one view, and connect the varieties of character with the alterations in specific gravity. It will, of course, be understood that the patient was subjected to medical treatment, and that perhaps many of the alterations may, in part at least, be attributed to the agency of medicine and the influence exerted by regimen upon the disease.

CLINICAL LECTURES ON MEDICINE,

*Delivered at the Meath Hospital, Dublin,
Session 187-8,*

BY PROFESSOR GRAVES.

LECTURE XIII.

Treatment of Syphilis continued.—Use and abuse of Mercury; with Cases.—On the causes which impede its beneficial action.—Corrosive Sublimate to be preferred in some cases.—Observations on authors. &c.

I HAVE stated, in a former lecture, that you may give mercury for syphilis in such an injudicious way, that all the efforts of the medicine are expended, not on the disease, which it is meant to cure, but on the constitution of the patient, which it injures. This proposition, whose truth has been long recognised, cannot be impressed too strongly or too clearly on your minds; for on accurately comprehending its scope and meaning will depend your success in the diagnosis and treatment of difficult cases. Nor is this peculiar to mercury when used in venereal disease, for the same mineral may be so mismanaged, in other diseases also, as to produce no beneficial effect, although it be the very best remedy that can be administered in them, when judiciously prescribed. Thus, give calomel in considerable and repeated doses to a dysenteric patient, and allow him at the same time to use cold and acid drinks, and a mixed diet with vegetables, and you will render the disease worse, instead of better, especially if the skin be freely exposed to alternations of temperature and cold air.

Again, when a violent pneumonia has hepatized a considerable portion of the lung, no remedy exceeds mercury in value; but it may, nevertheless, and I regret to say not unfrequently is, given under such circumstances, without the necessary precautions, and consequently rather injures than serves the sick man. The same observation applies to mercury when ordered in pleurisy or peritonitis, and is remarkably exemplified in arthritis and sciatica: in the latter disease, unless proper precautions as to temperature and rest are taken when giving calomel, you will be sure to salivate without obtaining any relief of suffering.

If opium be administered without tact, at wrong times, and in wrong doses, it often fails to procure sleep, and causes watchfulness, and so it is with all our remedies; they only produce a curative effect when properly exhibited. Certain states of the system, too, prevent the kind constitutional action of mercury. Suppuration of the liver renders it almost impossible to affect

the mouth, as has been remarked by Annesley and Marshall. When the constitution is eminently scrofulous, mercury rapidly gives rise to a new group of bad symptoms, and fails to cure the venereal cachexy for which it was given.

The presence of the scorbutic diathesis—and it often may be associated with syphilis—renders the use of mercury unsafe and even injurious; even in healthy constitutions the favourable influence of mercury on the venereal symptoms may be interrupted or destroyed by strong mental emotions, excessive fatigue, bodily labour (hence the difficulty of getting mercury to act well on day-labourers and artisans, while employed), irregularity of diet, intemperance, &c. &c.

In all cases where any of these causes operate on the system, it is extremely difficult to prevent the mercury from going astray (as it is termed), that is, injuring the constitution without serving the disease.

The following example proves the truth of this observation, and shews that a very great difference of opinion exists even amongst the most determined mercurialists, respecting the propriety of giving and withholding mercury in certain cases.

Mercury is a powerful medicine, requiring the greatest caution and skill in its administration: in the hands of such men as Colles, Crampton, Cusack, and many other practitioners of Dublin, it is undoubtedly an instrument of extensive application and of great utility; but when intrusted to the management of persons of less ability and less experience, it is hard to say whether it does more harm than good. Some years ago I was called to see a young gentleman who had recently contracted a chancre. His constitution was perfectly good, and I proposed to cure the sore without mercury. To this he would not consent, and consequently I thought it right to call in the aid of the family medical attendant. He advised the use of mercury, and we prescribed five grains of blue pill, three times a day, after a few days' preparation by means of confinement, rest, and low diet. By a mistake on the part of the patient's brother, he got five grains of calomel, three times a day, instead of five grains of blue pill. A rapid improvement in the chancre took place, and on the fourth day we found the sore nearly healed, but the mouth much more affected than we had anticipated. He had then taken one drachm of calomel. That evening some young friends came to his room, and persuaded him to join them in a supper of oysters, punch, &c. In the night a most violent attack of mercurial cholera, with colic, vomiting, and purging, came on, and

reduced him to a state of great debility. The mistake, as to the calomel, was now discovered; and, in consultation on the following day, his mouth being very sore, and the chancre spreading, it was agreed to use soothing measures, local and constitutional. At the end of a week, we found the sore on the prepuce perfectly stationary; it seemed neither inclined to spread nor to heal, while his mouth was still a little sore, and his breath foetid. My colleague now advised the resumption of mercury, which was accordingly used, both internally and externally. In about ten days, during which time he scrupulously followed our directions, his system was again brought under the active influence of mercury, but still the sore was stationary. My colleague still wished to go on with the mercury; I dissented, and another consultant was called in. This gentleman, although a mercurialist, thought mercury here inapplicable, and we therefore left it off. I now touched the sore with nitrate of copper, and, applying to its surface some felt of hat, a scab was formed, which adhered until the sore completely healed. Several years have elapsed, and the patient continues well. Here, then, was a case where two mercurialists of great experience differed as to the expediency of giving mercury. As authorities they might be deemed equal, and yet, at a particular crisis, their opinions were diametrically opposed—an occurrence alone explicable on the grounds that the principles which guide mercurialists are not so precise and certain as they profess them to be. Indeed, on many occasions, I have found the greatest discrepancy of opinion between mercurialists as to the length of time during which mercury ought to be continued after it has caused a primary sore to heal, in the same case one practitioner advising a mercurial course twice as long as that recommended by another. Occurrences such as these demonstrate that much still remains to be done in this department of medical science, and such errors should teach us all—for we all make them—the necessity of acknowledging, that, as yet, our opinions upon this subject are based upon no very firm grounds; and that consequently we should be tolerant of the opinions of others when they differ from us either in theory or practice. Toleration, such as I have recommended, is but too rare, and many seem incapable of arguing or lecturing calmly and philosophically on the subject of the treatment of venereal. Now in the case above related, it appears to me that the mercurialist forgot some of the rules laid down by the advocates of mercury. Let us reconsider it for a moment: a venereal sore is rapidly healing under the influence of fifteen grains of calomel daily; had a proper diet been observed, another day

would have completely healed the sore, but unluckily the patient commits a gross indiscretion of diet, and, suddenly after that, the sore spreads beyond its original dimensions, and continues obstinately to refuse to heal again in spite of the patient's ill advised perseverance in the further use of mercury. Under these or similar circumstances, the rule laid down by Matthias becomes applicable, viz. that when a sore becomes stationary (having been previously healing) or gets worse under the use of mercury, it is injurious to exhibit it any longer; it must be laid aside, until those causes which deranged the constitution, and impeded the proper action of the mercury, have ceased to exist. But to prove still further that the most strenuous supporters of the mercurial system are liable to errors—to grievous errors—I shall give you the following case, on the accuracy of whose particulars you may implicitly rely. The practitioner who conducted the treatment is considered to be a most skilful mercurialist, and most experienced in the management of syphilis. When the rules that should guide us in the exhibition of mercury prove so fallacious in such hands, how much more likely are they to fail with the young and inexperienced!

Mr. —, a strong, healthy, young man, got a small pimple and sore on penis after connexion, 25th Nov. 1836. He consulted a medical friend on the very day the pimple came out: he was assured that it was not venereal, and was desired to return on the 5th day; then also same opinion was repeated. Suspicious of its accuracy he went to another practitioner, who put him on alterative doses of mercury; Plummer's pill was continued for ten days without any soreness of mouth; it was then discontinued, as primary symptoms had healed. He remained quite well until February 1837, in the middle of which month three or four large tubercular pimples slowly formed and suppurated on the scalp, neck, and face. His general health, however, appeared quite good. On the second of March 1837, his throat felt a little sore, and he began sarsaparilla decoction; otherwise his health continued good. On the 16th March, however, a copper-coloured eruption, consisting of blotches variously sized and very numerous, came out on body and limbs. The eruption was unattended by fever.

He now consulted a third practitioner, who ordered him to rub in ʒss. of strong mercurial ointment, twice daily. His mouth became very sore on 5th day, when rubbings were discontinued for a few days, but were then resumed, and continued for seven weeks longer, during which time he confined himself to his room, and was very careful as to his diet. On the 11th May, the frictions were discontinued, as Mr. — pronounced

him cured, and safe from all danger of relapse. Observe that his month had been decidedly affected all this time; profuse salivation had not been maintained, but his gums were tender, and a slight salivation existed all along, after the violent salivation which arose on the 5th day had subsided.

The patient took great care of his health during the summer and autumn. He continued quite well until the 9th of September, when he got an ulcer in his throat. He again applied to Mr. —, who at first insisted (in self defence, no doubt) that the sore throat must have been occasioned by new infection. This the patient truly denied; on examining the ulcer Mr. — asserted that it arose from the original syphilitic infection, and he immediately put him on the daily use of a quarter of a grain of corrosive sublimate. He touched the ulcer several times with nitrate of silver in solution; the throat got well on the 7th day, but by way of securing the constitution, the quarter-grain daily dose of corrosive sublimate was continued.

On the 1st of January, 1838, another ulcer formed in the throat! Mr. — now increased the corrosive sublimate to half a grain daily, touched the ulcer several days in succession, twice daily, with butter of antimony; after some days only once daily.

On the 10th of January ulcer was healed. The use of the concentrated syrup of sarsaparilla was added, and the half grain of corrosive sublimate was continued until Friday, 2d March.

I need scarcely record that he was then in an extremely debilitated state, for the length of time he had been taking corrosive sublimate had been enough to impair the power of his stomach, so that for two months he had lost all appetite, and he was likewise slightly jaundiced. By the way, when mercury has been used by a patient to excess, jaundice is by no means an uncommon consequence—a fact we had often occasion to verify in the Lock Hospital 20 years ago.

The above case is instructive likewise, proving, as it does, that the same venereal poison in the same constitution may give rise to cutaneous affections of different species, for it here at first produced tubercular pustules, and at a subsequent period copper-coloured blotches.

When this patient was placed under my care I looked on him as a victim to a plan of treatment injudiciously persevered in for months after mercury was no longer necessary. Accordingly I discontinued that mineral altogether, and the patient completely recovered. It is difficult to imagine what train of reasoning could have misled the practitioner in this case. But to return to the causes which impede or prevent the beneficial action of mercury.

Every excess—every thing in fact which injures the health of body or mind—will have a tendency to counteract the beneficial effects of mercury on the disease. I think much mischief has been done by the well-known assertion of John Hunter, that he could not see what harm a good dinner and a bottle of wine would do to a man taking mercury for chancre. I would not advise you to undertake to administer mercury in venereal cases unless the patients are willing to submit to your directions;—be careful in matters of diet, avoid intemperance, and confine themselves to bed, or at least to their rooms.

Many have proposed the question—whether the poor are served or injured by Dispensary practice? Whatever may be the case with respect to the others, there can be no doubt that the venereal patients are injured. In proof of this assertion, gentlemen, I have to request your attendance at some dispensaries in winter. See the crowd of squalid, wretched, and too often depraved applicants who throng around the prescriber: observe his examination of twenty or thirty venereal patients in succession; a single glance of his eye determines the nature of each case, and a single scratch of a pen its treatment; to all—all indiscriminately—he gives mercury, no matter whether they are clothed in rags, and exposed day and night to damp and cold—and no matter whether they work hard and live by the sweat of their brow, they must all use the same pills and ointment.

It is the subjection to strict regimen, quietude, and confinement, which seems to act so favourably in the case of soldiers. They are confined to hospital, obliged to keep their beds or rooms, deprived of all dietetic stimulants, and removed from all causes of mental emotion, and hence it is that their chancres heal so rapidly. Mercury will seldom do much good unless taken under proper regulations. It will affect the constitution variously, but in general injuriously. I have already mentioned one case in which it acted injuriously, in consequence of indulgence: allow me to give another case of the kind arising from a different class of causes. A young gentleman at college, who was under my care for chancre, was taking mercury for some time during the summer season. He had taken some blue pill with benefit, and thinking if one or two pills were good, a large number would be better, took them much oftener than he was ordered.

An election took place at the college; he went to see it; became actively engaged in it, and continued so until a late hour in the afternoon. The weather happened to be extremely warm, so as to oblige him to change linen three times during the day,

but the excitement produced by the election was such, that he forgot the condition he was in, exposed himself to a vast deal of fatigue, and remained fasting the whole day. In the evening he went home, and took a large glass of wine. In the course of a few minutes his head was violently affected, he became quite delirious, and continued alarmingly so for twelve or fourteen hours. Here you perceive the mercury affected the head, producing violent delirium. In other cases it will give rise to coma. In fact, it would be difficult to enumerate the various modes in which it may act injuriously when administered without caution, or when the patient is exposed to disturbing influences during a mercurial course.

You will recollect that some time ago, in speaking of double or complex diseases, I brought forward several facts in support of the hypothesis, that persons may labour under several diseases at the same time, all of which may combine to form an impaired state of the general system. In confirmation of this assertion, it appears that mercury may be employed for the treatment of syphilis, as not only to leave the disease untouched, but also to superinduce mercurial cachexy, and even scrofula, and in this state you may have eruptions of various kinds. This is one of the worst forms of complex disease that comes under the notice of the practical physician. It was this form of disease which exhibited so many melancholy spectacles in the Lock Hospital some years ago: patients were seen labouring under all the horrible symptoms which combined syphilitic, scrofulous, and mercurial cachexies present: the glands, skin, throat, bones, mucous, synovial, and fibrous tissues, were all simultaneously affected; in fact, almost every tissue in the body was more or less engaged, and the patients died terrible examples of the frightful ravages of complicated disease.

In endeavouring, therefore, to analyse the nature and character of syphilis, you must always hold one great object in view, viz. to ascertain as closely as possible the order of the symptoms. Let us, for example, take the case of the woman in the chronic ward, who is at present labouring under nodes. The first object here is to inquire whether they are syphilitic or mercurial; and with this view, it will be necessary to obtain an accurate history of her case—to ascertain the order of symptoms—how long and in what manner she used mercury—what relief she has obtained—and whether the symptoms of relapse have come on slowly and gradually, or rapidly and at once.

If a person labouring under a certain class of symptoms, primary or secondary, has used mercury until his mouth has been affected, and if, when he has reason to think

himself cured, his mouth being still tender or lately so, if such a person after exposure to cold gets a violent attack of pains followed by periostitis, we may conclude that such a person has taken a sufficient quantity of mercury to cure his syphilis, and that his complaint is mercurial periostitis; for here you have a train of symptoms not referrible to the original cause. This is a very common case, and you will see numerous instances of it in labourers, and persons who are exposed to atmospheric vicissitudes while taking mercury. You will find on inquiry that after they have been cured of the venereal symptoms, they have exposed themselves to cold while still under the influence of mercury, and have shortly afterwards been attacked with a new train of symptoms. In most cases the chances are that this sudden supervention of disease is not the effect of syphilis, but of mercury. An accurate analysis of the history of the case, and a careful observation of the new phenomena, are then the only guides we have to enable us to arrive at a just conclusion. I stated at my last lecture, that the mere fact of a considerable time having elapsed since the patient took mercury is no proof that the symptoms are not mercurial. I have over and over again met with cases of periostitis in persons who had been two, four, six, and even eight years, without taking mercury. I was called the other day to see a lady whose mouth was sore, and her breath fetid; in fact, who presented all the phenomena observed in cases of mercurial salivation; and yet it is now several years since she took mercury, by the advice of an eminent Dublin physician. Now if so much time could have passed by, and yet one of the immediate effects of mercury be present, it is not improbable that some of its remote effects should appear after a lapse of time in which we would suppose that the mercury had been completely removed from the system. Many facts, however, can be adduced to shew that some constitutions, when thoroughly affected by mercury, are apt to retain it for a very considerable time, and hence the practical physician is led to the reflection that it should be used only in cases of necessity, and with all due discretion. Thus, in treating rheumatism, if you can cure by bleeding, leeching, tartar emetic, Dover's powder, and colchicum, you should not have recourse to mercury. The same observation will apply to the treatment of pneumonia, hepatitis, and many other forms of inflammation.

In a letter which I have just received from Sir James Macgrigor, he informs me that mercury is very little used in the army. There is no regiment or hospital from which it is wholly excluded; but it is

administered with discretion, and only when the necessity of the case plainly requires its employment. I may here observe, *en passant*, that you will find some excellent observations on mercurial remedies in the lectures of Dr. Sigmond, published in the *Lancet*.

There is one remark I wish to make with respect to mercurials, namely, that an undue preference is shown to some preparations, to the exclusion of others. I think, for instance, that calomel is too often employed where other preparations would answer better, and that corrosive sublimate is too much neglected. I have witnessed its superiority to other preparations of mercury, in many instances; and some practitioners prefer it in the treatment of many forms of secondary syphilis. Thus, in a patient labouring under secondary symptoms, after the fever is over, and the eruption begins to decline, corrosive sublimate may be used with great advantage. One-eighth of a grain may be given twice a day, and every night the patient may rub in from a scruple to half a drachm of mercurial ointment. Under this treatment the disease is cured much more rapidly and effectually than if calomel or blue pill, or mercurial inunction alone, had been employed.

In throwing out these few observations on the treatment of venereal, my object has not been to enter into specialities, but simply to furnish a few general rules for the guidance of persons engaged, or about to be engaged, in the treatment of one of the most important diseases in the whole nosology. You will find any additional information you want in books. An immense quantity of valuable information has been collected by the army surgeons; and—thanks to the indefatigable industry of Sir James Macgrigor—the profession and the public are now able to avail themselves of those valuable contributions to medical science. You will find much valuable matter in the *Medico-Chirurgical Review*, the last number of which contains an able analysis of Mr. Colles's work on Venereal.

Ricord's work has been very ably reviewed in the *Edinburgh Medical and Surgical Journal* for July 1838; and to that periodical I must refer you for details, merely remarking, that no modern author has done more than Ricord, by contributing materials calculated to decide many important controverted questions.

Fricke remarks, that although affections of the bone and periosteum are a very frequent effect of the syphilitic poison *per se*, yet caries and destruction of the bone are seldom or never observed, except when mercury has been administered. This observation is, generally speaking, correct; but,

nevertheless, it requires some limitation—for I have seen examples of caries of bone in the venereal disease, where not a grain of mercury had been taken. In the cases I allude to, the scrofulous diathesis was pre-eminently marked, and the affection of the bones, which the venereal poison excited, immediately degenerated from its usual course, and assumed all the characters of scrofulous disease. In both instances, destruction of the nasal bones, and consequent sinking in of the bridge of the nose, occurred—a deformity occasionally of simple scrofulous origin.

From an analysis of Pirogoff's "*Surgical Annals*," published in *Oppenheim's Journal*, September 1838, it appears that mercury is very seldom employed at Dorpat for the cure of venereal, and yet Dorpat is remarkable for the number and severity of syphilitic cases—a circumstance partly attributable to the absence of medical surveillance over the women of the town, and partly to the apathy, carelessness, and filth of the lower orders.

Pirogoff's general mode of treatment is non-mercurial; and he maintains that relapses are less frequent and less violent than when mercury is employed as the general means of cure. It is worthy of remark, that a peculiar consequence of phymosis, or its causes, is frequently observed at both Dorpat and Petersburg, and which consists in the transformation of the inner layer of the prepuce into cartilage. There is no remedy for this but circumcision. This change into cartilage is always produced by diseases which, producing phymosis, at the same time give rise to a long-continued irritation and inflammation of the inner surface of the foreskin, attended with an increased secretion from the latter. Under such circumstances, the surfaces of the gland and its covering prepuce pour forth secretions of an offensive nature, and which find a very difficult vent, and are, besides, rendered more acrid by an occasional admixture of urine, and by the impossibility of thoroughly cleansing the parts.

This conversion of a submucous cellular layer into cartilage occurs also in the intestinal canal. In March, 1831, two examples of it were observed by Dr. Nalty and myself at Sir P. Dun's Hospital. One of these cases was very remarkable, as the submucous cellular tissue of the colon was converted into cartilage over an extent of eight or nine inches in length, and occupying the whole circumference of the gut in that part, so as to form a complete cartilaginous cylinder, about a line in thickness. This tract of intestine seemed therefore formed of four distinct coats, viz.:—mucous, cartilaginous, muscular, and serous.

The cartilage was firm in its structure, very pliable, though strong, and its deposition seemed to have produced no change in either the calibre or shape of the intestine. This morbid production was evidently connected with a chronic inflammation of the mucous membrane, which had finally terminated in numerous ulcerations, and was accompanied by a copious deposition of black colouring matter, giving the membrane a mottled appearance. The blotches of black occupied by far the greatest portion of the surface, and was of very deep shade, precisely similar to the colouring matter so often found in the bronchial glands and on the surface of the lungs.

In the healthy European this black colouring matter is not found, except on the surface of the lungs, and in the chorion, where it forms the pigmentum nigrum. In the negro this colouring matter occurs likewise in the rete mucosum, producing the black skin which distinguishes that variety of mankind. We thus see that in the white as well as the negro, not only do the vessels of certain organs enjoy a power of secreting black colouring matter during health, but that likewise during disease other parts of the body, as in the cases I have cited, may assume a similar action, and secrete black matter. In some whites this tendency to secrete black matter becomes excessive, and gives rise to certain forms of melanosis, where this matter is secreted in almost all the tissues of the body; for I cannot agree with Faudrington in thinking, that the experiments of M. Barruel, or those of Dr. Henry, are sufficient to establish a marked difference between the colouring matter of melanosis and that of the rete mucosum of the negro, or the pigmentum nigrum of the white. The melanotic patches are, no doubt, often of a different shade, but very frequently they are extremely black.

Be this as it may, the black matter in the intestines I have described was clearly of the same nature as that on the surface of the lungs of the white, or the rete mucosum of the negro. This subject is interesting, because a knowledge of the fact, that the black colouring matter which imparts to the skin of the negro its peculiar hue, is also a natural secretion in certain organs of the white during health, and is likewise in the latter a frequent product of disease—I say a knowledge of this fact is of great weight, proving that the black colour of the skin cannot constitute a difference of species. With regard to the hair, which is often the seat of a probably similar colouring matter in the white, I may observe, that one fact, not hitherto attended to by physiologists, is in itself sufficient to establish that the hair is a

horny tissue, in which a certain circulation is maintained. The fact to which I advert is, that the hair often begins to grow grey at its extreme point, or the end furthest from the root. Here the colouring matter is often absorbed, while it still remains in the remaining portion of the hair. The phenomena of *plica polonica*, so admirably described by my friend, Dr. Kowalowski, in the *Dublin Medical Journal* for November 1838, establishes the vitality of the hair.

CLINICAL REMARKS ON LITHOTRITY.

By MR. MAYO.

Being Part of a Lecture delivered at Middlesex Hospital, March 25.

THE following account of a case of stone treated by lithotrixy, which has recently been brought to a favourable termination in the Middlesex Hospital, will serve to form a clinical supplement to the general observations on that subject which I have addressed to you in my course of surgical lectures.

Wm. Blake, aged 54, a farmer's labourer, of a ruddy healthy complexion, in person rather spare than full, was admitted on the 9th of January, 1839, for stone in the bladder. The symptoms had commenced two years previously. While engaged in threshing, about Christmas 1836, he first remembers to have experienced uneasiness in the bladder, and frequent urgency to void the urine. He noticed that the urine was often thick, and sometimes red. For some time he continued much the same; he was sometimes better, sometimes worse, as his occupations required more or less bodily exertion. He suffered particularly during the reaping season last summer. At length the irritation of the bladder and pain after making water became so serious, as to compel him entirely to relinquish work. He then came to the hospital. When sounded at his admission, the stone was ascertained to be of small size, and single. The urethra was free, and allowed a full-sized instrument to be introduced into the bladder. He was desired to remain in bed; the half diet of the hospital ordered for him, aperient medicine to be given when necessary, and the decoction of *uva ursi*, with ten grains of carbonate of soda, to be taken twice daily. In a few days

his symptoms were mitigated; he could retain the urine longer in the bladder, and had less pain after passing it. At the expiration of ten days he seemed to have reached a maximum of improvement. He could now hold his water for several hours, which was not of a much deeper colour than natural, and contained but little mucus.

Every circumstance in this case appeared to render it suitable for lithotripsy: the smallness of the stone, the large calibre of the urethra, the presumable healthiness of the bladder, the good constitution of the patient. I accordingly performed that operation in the manner which I will describe.

The patient, being half dressed in drawers and stockings, sat down at the foot of his bed on two pillows, and was then assisted to fall back, another pillow being placed to support his head: his knees, at the same time, were bent, the feet resting on the floor, and the legs held each by an assistant, so as to prevent his slipping backwards off the pillows, which were intended to keep the pelvis raised. As the operation was done at one o'clock in the day, and he had passed no water since eight in the morning, and said that his bladder was full, it seemed unnecessary to inject water, which I thought it probable the bladder would not retain. So I passed at once the crushing instrument invented by Baron Heurteloup into the bladder, and, having felt the stone, opened the blades and seized it. One eminent advantage of this instrument is the facility with which the stone is caught. The stone, of course, lies at the lowest part of the bladder; and the lowest part of the bladder, through the position of the patient, is at the same time the most easily accessible by the instrument. The instrument being opened by drawing upwards its upper jaw, the lower part remains at the lowest part of the bladder, or where the stone is. If the stone is now lightly tapped, it moves aside, but immediately returns to the lowest part of the bladder—that is to say, to where the under-jaw of the instrument lies, on which it necessarily places itself: upon pressing down the upper jaw of the instrument, the stone is therefore, as you saw, caught with certainty.

The next step consisted in drawing the instrument away from the posterior surface of the bladder towards its centre, rotating the instrument at the same

time to either side, to be sure that it had hold of nothing adherent.

Mr. Chalmers, my dresser, then grasped the instrument with a strong hand-vice, made by Messrs. Everil and Mason, and thus fixed the instrument in the position it had been placed in. He was desired to attend to nothing but the position of the instrument in reference to the man's body; so that if the patient moved, his hand and the instrument should move with him, or otherwise be perfectly motionless.

I then turned the lever which moves the screw of the instrument (the preparations already described being such as to enable me to use either the screw or the hammer for crushing the stone, as might appear expedient in the progress of the operation). The stone was heard and felt to break into fragments, very moderate pressure being used; the jaws of the instrument were closed by the use of the screw only. The stone, or a part, was seized a second, third, and fourth time, and each time broken; and a catheter with large eyes was then introduced into the bladder, the urine allowed to flow out, and a syringe of warm water gently injected. A few fragments came away.

In the night a smart rigor supervened, followed by a hot stage the next day. There was no tenderness of the hypogastrium, but the urine was high-coloured and turbid. The patient was placed on low diet, an opiate with calomel given at night, and a laxative dose the next morning. In a few days he was as well as before the operation.

A week afterwards I repeated the operation, with the difference only of injecting some water into the bladder before introducing the crushing instrument. The patient passed the following night in a heavy sleep, and on waking had a return of symptomatic fever, which lasted several days, during which, however, singularly enough, the patient voided highly-coloured and turbid water entirely without pain. The result of this second operation made me apprehensive that it would prove necessary to relinquish lithotripsy in this case, and led me to anticipate that it might be preferable, as soon as the patient's health should be again restored, to resort to lithotomy.

However, when three weeks more had elapsed, and the patient seemed in as good plight as before the first opera-

tion, I resolved to repeat the same once more with every possible precaution, taking measures to disturb the bladder less than before, and determined to be satisfied with doing very little at each sitting.

The operation was therefore performed with the following points of difference. The bladder was first injected with warm water, so as to be as full as the patient could bear; but the catheter used for this purpose was not introduced into the bladder, but only as far as the membranous part of the urethra. I seized and broke the stone, or fragments of the stone, three times only, and immediately discontinued the operation; and no water was injected into the bladder afterwards. This time no unfavourable symptoms followed. The urine, indeed, became of a higher colour, and contained more mucus for twenty-four hours, and the pain after voiding the urine was greater for the same time; but there was no symptomatic fever. During the ensuing two days many fragments came away.

This operation, performed on a Saturday, was repeated the three following Saturdays, the last being March 17th. After each many fragments came away; after each successively the pain was less, not merely that resulting from the operation, but the habitual uneasiness in the bladder on voiding urine. After the last, which was followed by the passage of more fragments and sand than usual, all the symptoms entirely disappeared. Upon most carefully sounding him twice since, at intervals of four days each, and drawing the water off through a large catheter, it is evident that no fragment remains in the bladder, and that the patient is really as well as he believes himself to be.

The stone, it appears, from the shape of the fragments, was a flattened oval; the nucleus was composed of lithic acid; the exterior part of the phosphates. The weight of the fragments that were preserved is two drachms thirty-nine grains. The patient says that as much again has come from him when making water at the water-closet, and in sand, which was not collected. Perhaps the stone weighed a third more than the fragments which are in my possession.

This case, taken in any view, cannot be considered as uninteresting. It is possible that the washing out of

the bladder, practised on the two first occasions, may have been injurious, and that avoiding passing the catheter into the bladder in the preliminary injections afterwards, may have been serviceable. At the same time, I hardly think that these elements of the operation can have much modified the result; and the most important step, as it appears to me, taken in the management of the case, was the interval interposed between the second and third operations, during which the patient was kept in bed, and general means used to lessen the susceptibility of the bladder. It is not impossible, that if the patient had remained a month under treatment, before any operation, no symptomatic fever would have followed on the first trial. It is equally evident, that if the operation had been repeated without that interval, and in spite of the recurrence of symptomatic fever, the patient's life would have been sacrificed, although the stone might all have come away before his constitution sank under the consequences of the treatment.

The great advantages of lithotripsy are, that, with a certainty of success in the majority of cases, in all the surgeon can stop short of inflicting serious pain, or risk of life.

ON THE EAR.

NO. II.

To the Editor of the Medical Gazette.

SIR,

IN my last, I stated that the jets of air used by Dr. Deleau, would tend to force the more liquid obstruction of the Eustachian tube and cavitas tympani into the mastoid cells, where it would produce considerable mischief. Dr. Deleau, in another part of his work, acknowledges that the results of jets of water into the Eustachian tube are great pain. Now jets of air, upon an obstruction of the above description, would occasion similar results; and the previous extraneous matter, as far as the mastoid cavernulæ are concerned, would excite inflammation of the mucous lining of those cells. The pus thus formed having no outlet would be productive of pain; and as the accumulated matter became more and more acrimonious, the delicate

septa forming the divisions of these cells would be broken down and destroyed, and large tumefactions be formed upon the mastoid process, which would require to be opened to afford a passage to the pus.

This state of the parts often occurs from inflammation of the *cavitas tympani*, which extending to the Eustachian tube, reduces its calibre, so as not to allow the pus to pass off that way, the consequence is, that the mastoid cells become gorged with the pus, and all these evils in a greater or lesser degree follow.

I had an extreme case of this description about nine years ago, in a lady, named Jones, of Carmarthen; the tumor had been opened in the country, the discharge from the opening remained, was much discoloured, and sometimes streaked with blood; the whole of the septa of the mastoid cells were destroyed. Sir Astley Cooper saw the case with me. An injection through the above opening of nitric acid, *gtt. ij.* with distilled water, *℥j.* which passed into the *cavitas tympani*, and thence into the mouth by the Eustachian tube, removed the tendency to discharge, and she has since remained free from any unpleasant symptoms. In this instance the lady suffered dreadful pains for some weeks previous to the tumor having formed, but those pains subsided, and no doubt the Eustachian tube became pervious when another outlet for the pus was formed, as I have mentioned on the mastoid process.

I have seen several cases of a similar nature, and in the early stages should puncture, with a guarded spear-pointed instrument, the *membrana tympani*, to allow the pus to escape into the external auditory passage, from whence it could be dislodged by the syringe and warm water.

The above are, I conceive, strong objections to Dr. Deleau's mode of practice, which appears to me unscientific, even if he succeed in performing all he purposes; but I much doubt whether in withdrawing the mandral or wire from the elastic tube, he do not displace the tube altogether. A scientific gentleman, who submitted himself to the operation under Dr. Deleau's hands, told me afterwards, that he was certain the elastic tube did not enter the gular orifice of his ear at all the first time it was passed through the nose;

and, on the second attempt, he thought it did so; but on the Doctor removing the curved wire, the elastic tube was displaced. He gave Dr. Deleau fair opportunities, but derived no benefit. The case was afterwards cured by attention to diet, and applications to the external auditory passage, with frequent repetitions of gargles, used as I before described.

A lady, named Shewell, residing at Philadelphia, applied to me by letter for advice more than a year ago. She had been a patient of a Dr. Tôgno, who practised in America upon Dr. Deleau's principles. Her description is as follows:—He commenced by giving an emetic three times a week; then inserted a gum elastic tube, containing a crooked silver probe, through the nostrils; next drawing out the silver wire, he connected the gum-elastic tube to one attached to an air-pump, holding the nose and mouth close with the hand, and inflating, as he said, the Eustachian tube. This process was repeated *twenty-five* times. Finding the deafness much more intense, he then advised cephalic snuff, and a gargle of decoction of *ipeacacuanha* twice a day, to produce nausea, and thus draw down, as he said, the mucus collected in the channels: he then directed an infusion of herbs to be prepared; the patient was placed in a tub covered with a blanket, and hot bricks were thrown into the infusion, till a profuse perspiration was induced. The lady says, previous to these methods being tried upon her she could hear a watch tick several inches from her head, but now she cannot hear it if applied close to the ear. I have not yet seen this lady, but expect to do so, therefore cannot at present say what may be the nature of her case.

French surgeons make a great deal more preparation than we do, previous to attempting the cure of common deafness; and in cases of puriform discharges, commence with an issue or seton in the nape of the neck; the patient taking in the morning, fasting, on alternate days, three glasses of tar water, and the next two glasses of spruce beer. Eight to twelve *ipeacacuanha* lozenges, two at a time, between breakfast and dinner, so as to produce nausea; while from the month of March to that of May, juice of cress, chervil, and scurvy-grass, equal quantities, are taken in place of the tar water and

spruce beer. During the months of July and August, baths of and drinking sea water; but if that be not possible, baths of the artificial waters of Barèges. Injections into the auditory passage of lime-water one-third, and milk two-thirds, until at about the end of two months, when, if there be no pain, the lime-water is to be used pure. Flannel worn all over the body, next the skin; diet, roast or broiled meat; no shell fish, pastry, nor green fruit.

Dr. Deleau gives several cases which were treated in a similar manner by other medical gentlemen, who, according to him, were in error, as he cured the patients completely and speedily by jets of air into the Eustachian tube.

I am, sir,

Your obedient servant,

W. WRIGHT,

Surgeon Auriat.

13, Salisbury Square, Fleet Street,
March 23d, 1839.

CARCINOMA MAMMÆ.

To the Editor of the Medical Gazette.

SIR,

SHOULD the following case be considered of sufficient interest to bear a place in your valuable journal, an early insertion will much oblige

Your obedient servant,

HUGH BIRT, M.R.C.S. &c.

Ashington Stonington, Sussex,
March 27, 1839.

Mrs. Thomas Hews, ætat. 45 years, recently a resident of Stonington, of diminutive stature, and of a nervobilious temperament, requested me to examine her left breast, in May 1838. On complying with her request, I discovered a large indurated tumor, occupying nearly the whole substance of the mamma, painful on pressure, and slight discoloration of the cuticle a little inferior to the nipple, which was slightly retracted; the discoloured surface was circumscribed, about the size of a shilling. On examining the glands of the axilla, I could not detect the slightest induration or enlargement, but, on the contrary, was led to suppose them perfectly free from any morbid influence.

At times she suffered most excruciat-

ing pain in the breast. She imputed its origin (the tumor) to a blow received on the breast three years since. She has never had any family, or even been impregnated, although married for the last 14 years. Her catamenial discharge had been always perfectly regular, although small in quantity. She states that she has experienced more bodily affliction in the last three years (previous to the operation), than in the whole of her life besides. She appeared to labour under indigestion, with all its concomitant symptoms—with hepatic obstruction, producing very inefficient chylickation and defecation. She had taken iodine for a long time, and had been under two hospital surgeons (metropolitan), without experiencing any relief or even mitigation of her sufferings. After a short course of blue pill, with laxatives, bitters, and alkalies, with a view to correct the morbid gastro-intestinal action, I obtained her consent to remove the diseased mamma, which was performed in the usual manner, in the presence of two intelligent professional friends. I took very great precaution in removing (in fact, clearing out) all the small glandule congregated situated under the inferior margin of the pectoralis major muscles, leading to those of the axilla; and I am perfectly satisfied if this precaution was always attended to in these cases, we should be more successful in the total eradication of this malignant malady. The arteries were very large and numerous, and appeared to be branches principally from the arteria thoracica descendens; their coats were extremely brittle, and, as I afterwards discovered, were partly ossified. My patient lost but little blood, and recovered rapidly from the effects of the operation: her digestion is and has been very good since; and the glands of the axilla and other surrounding parts appear perfectly healthy, and free from any morbid influence. Why may I not reasonably expect I have exterminated the disease? On examining the tumor, I found it to present the well-known pathological appearances of carcinomatous or rather scirrroid disease—glistening, pearly, and striated. Had it remained but for a short time longer, its ulcerative stage would have been established, when all our efforts would, I believe, prove useless in attempting a cure; for the communication to the glands of the axilla would have been

the direct road for the "contaminating virus" to have travelled into the system; thus exposing it to the greatest "ill flesh is heir to." The family have suffered from cancer for generations past; thus affording another proof that the ills of our forefathers descend on the heads of their children.

URINARY CALCULUS.

To A. C. Hutchison, Esq

MY DEAR SIR,

I WAS duly favoured with your letter, and with much pleasure forward to you the particulars respecting the calculus which I placed under your notice a few months since, in my museum at our Infirmary.

John Huggins was a native of Ship-ton Mallet, which is near the city of Wells, in Somersetshire. He had decided symptoms of a vesical complaint from his earliest recollection. In June 1831 he was 53 years of age. At this period the calculus was removed by the lateral operation, by my colleague, Mr. Richard Lowe. It is globular, the diameter being one inch and a quarter. The quarter of an inch appears to be a newly-deposited layer. It is phosphate of lime, all the rest being a pure mass of oxalate of lime; in fact, a regular, ordinary, mulberry stone. The whole weighs two ounces and two drachms. Being the immediate assisting-surgeon at the operation, I was close to the patient, when, a few minutes before it commenced, the man turned to me, and said, "Sir, I was like this, and upon this very table, twenty-seven years ago." Of course my curiosity was aroused. "Indeed," said I, "how so?"—"Why, sir," rejoined the man, "I was your patient, and you put me here, and found a stone, and the operation was to be the next day."—"Well," said I, "how was it I did not cut you?"—"Because," said Huggins, smiling, "I cut you!—that is, I was frightened, put on my clothes early in the morning, and when the doors were opened I ran away."—"Well, what became of you?"—"I entered as a seaman on board a man-of-war, and I served on board the Monarch line-of-battle ship eight years, and was in the north seas with Admiral Duncan. I fought a gun in the action off Camperdown,

when we leathered De Winter, and took the Dutch fleet."—"Well," said I, "and did you find nothing of the stone?" "Not a bit, sir, I never had the least pain for twenty-six years; but about a twelvemonth ago it began to be troublesome, and is now so bad, that I am resolved to get rid of it, and so here I am again."

Now the man's story is borne out by dates. The battle of Camperdown was fought in October 1797, and at that time I had been elected surgeon to our hospital sixteen months, a circumstance which the man could not have known, and besides that, he had no object whatsoever in telling a falsehood. The ship was a 74, and of course the running in and out of the guns a severe duty.

The despatch says, "Admiral Onslow, in the Monarch, bore down on the enemy's rear in the most gallant manner, and had 136 men killed and wounded." So that it must be confessed there was work enough done on board of her. Perhaps the minute account which I have given of the conversation may excite some surprise at the faithfulness of my memory. The fact, however, is, that during the last forty-two years I have been in the habit of making memoranda *instantly*, and entering them in a book kept for that purpose. I can, with rare exception, therefore, refer to all that I need. I register the patients, the birth-place, age, how long ill, how many brothers and sisters, whether troubled with any other disease, and also father and mother, date of operation, operator's name, result. Of the calculus, the weight, and chemical analysis, together with the names of the officers of the house, students and strangers who were present. Some of this may appear a work of supererogation: but I assure you, that in after-life many practitioners are pleased in looking over the museum with a friend, to see their names, as pupils, registered upon the back of the card to which the divided calculus is attached, and also its history.

And now, my dear sir, I have only to add, that I do think the case of Huggins tells strongly in favour of your views, as to the influence of the sea in calculus complaints.—I remain,

Very truly and faithfully yours,

RICHARD SMITH,

Senior Surgeon, Bristol Infirmary.

33, Park Street, 28th November, 1838.

ON THE EXHIBITION OF REMEDIES IN THE FORM OF VAPOUR*.

By D. J. CORRIGAN, M.D. &c. &c.

THAT inhalation, as a remedial process, may obtain a fair trial, it is requisite,

1st. That the apparatus should be simple in its construction, and easily kept in order.

2d. That it should be capable of keeping up a supply of vapour for any length of time, and that the evolution of the vapour should be steady, and should be easily regulated.

3d. That it should also furnish a sufficient supply of aqueous vapour, to prevent any irritation of the larynx or lining membrane of the air-tubes.

4th. And most important of all, that its employment should entail neither trouble nor fatigue on the invalid.

I believe all these conditions are fulfilled in the following apparatus (*vide* drawing):—There is a light open iron-wire frame, about eighteen inches in height; at the bottom is a spirit lamp (A). At the proper height above it is an evaporating porcelain dish, about six inches diameter (B). Above this is a glass globe (C) with its neck downwards. In the neck of the globe is a cork (D) bored, and through the opening is drawn, moderately tight, a short plug of cotton wick, such as is used in a spirit-lamp; in the glass globe at (E) opposite the neck is drilled a pin-hole, to allow air to pass in, according as the fluid within drops out, through the neck. To use it, the porcelain dish is filled with hot water, the spirit-lamp is lighted, and as soon as the water in the dish has begun to boil, the glass globe containing the tincture of iodine (if this be the substance used) is placed as shown in the sketch. The rate at which the fluid in the globe shall percolate the cotton wick, and drop into the hot water underneath, is easily regulated. If it do not drop with sufficient rapidity, one or two of the threads of the cotton are to be removed. If it drop too rapidly, this is corrected by pressing in the cork more tightly, or introducing one or two additional threads of wick †.

This apparatus fulfils, I think, all the conditions required. It is simple in construction, and most easily regulated; there can be no sudden and injurious evolutions of vapour from it, but drop by drop, the evolution gradually and steadily goes on; and the air which the patient is breathing may be maintained in any required degree of impregnation, while the impregnation can be kept up for any length of time. The medicated substance employed is always vaporized with a sufficient quantity of aqueous vapour, to prevent any irritation of the larynx or lining membrane of the air-tubes; and lastly, employment of the apparatus for any duration entails neither trouble nor fatigue on the invalid.

Diffuser for the administration of Iodine, Chlorine, &c. in the form of vapour.

With this apparatus, the impregnation of the air of even a large chamber is so perfect, that the window-curtains are tinged blue by the action of the vapour of iodine. Solution of chlorine, the balsams, turpentine, preparations of camphor, stimulating or sedative remedies may, by this apparatus, be diffused in any quantity through the air which a patient is respiring.

I have mentioned the necessity which exists in most cases, of combining with the process of evaporation a sufficient quantity of aqueous vapour, to prevent any irritation of the larynx, or mucous

* From the *Dub. Journ. Med. Science* for March.
† To use chlorine, pour into the glass globe 8 oz. of saturated solution of chloride of lime, and into the water in the porcelain dish 2 oz. of the dilute sulphuric acid of the Pharmacopœia. As the chloride drops, the acid seizes on the lime, and the chlorine is evolved in connexion with the aqueous vapour.

membrane of the air-tubes. A few observations will shew the importance of attending to this. We are all familiar with the injurious effects of a dry easterly wind on irritable lungs, and we are equally cognizant of the beneficial effects which patients, suffering under such, derive from long sea voyages, during which they are inhaling air, which, sweeping over a great extent of sea-surface, must come to their lungs, holding in solution a large proportion of aqueous vapour. The following calculation, for which I am indebted to an American physician, whose name I regret I cannot recal to my mind, places the difference between the two kinds of air in a very striking point of view:—

If a man breathes twenty times per minute, and draws in at each respiration forty cubic inches of air, he will respire in twenty-four hours 1,152,000 cubic inches of air. The dew point of the human breath is always the same, it is 94° of Fahrenheit, and 1,152,000 cubic inches of air, the quantity respired in twenty-four hours, contains at 94° , 10,828 grains of water, or aqueous vapour. Suppose, now, air, which we are respiring, to be so dry, such as an easterly wind in this country may be, to contain so little aqueous vapour as to have its dew point as low as zero, the same quantity of air will then contain only 518 grains of watery vapour. This dry air, which, when entering the lungs, contains so small a portion of aqueous vapour, leaves them on expiration with its dew point at 94° , that is, it now on leaving them contains 10,828 grains of watery vapour. It has therefore abstracted the difference between 518 and 10,828, being 10,310 grains (or nearly two pounds weight) of watery vapour from the lining membrane of the lungs in twenty-four hours. To meet such an expenditure of the natural vapour of the air-tubes there is necessarily a constant determination of blood to the vessels of those tubes, and just as the dry air of the desert will, by robbing the parts of their natural moisture, inflame the eye and parch the throat, so will air, destitute of a due proportion of aqueous vapour, produce irritation and injury in the delicate and moist texture of the lungs.

Any lengthened observations on the therapeutic application of the apparatus which I have described, I must reserve

for a future time. The period is too short since its construction occurred to me, to permit me to say much as yet of its effects. The use of such an apparatus is principally required in chronic affections of the lungs; and these must be observed, both on a large scale and for a length of time, before we should venture to pronounce an opinion. The only remedial agent I have yet employed with the apparatus, is iodine. Connected with its employment there are some circumstances of which, however, I can even now speak with confidence. The inhalation of iodine has been dreaded, because in some instances troublesome irritation of the larynx has followed its use; this injurious effect has resulted from the defective means of inhalation hitherto employed. Used in the manner I have described, gradual in its evaporation, and intimately combined with a large portion of aqueous vapour, its use is positively (and I can say it with confidence) free from any injurious irritative effects. The vapour of iodine diminishes most remarkably the profuse and wasting purulent expectoration of phthisis. In the case of a man, named Carroll, with whom I have been using the apparatus in Jervis Street Hospital, the purulent expectoration, which had been very profuse, diminished soon after he commenced its use, to three or four sputa in the day; and thus it remained up to the time of his leaving the hospital in January. In this case, also, the constitutional symptoms accompanying phthisis were completely arrested by its employment. The physical signs of phthisis were also less extensive; but they had not disappeared when he passed from under my care. The effects of iodine thus used, on the digestive organs, have been very gratifying. In all the cases in which I employed it, the appetite and state of the intestinal canal have been improved. It has in fact acted as a most useful tonic to the digestive organs, without any of the irritation which its internal use in the ordinary form has often produced. It has also so much alleviated cough, that the patient has been enabled to obtain hours of sound and refreshing sleep. Even should its use prove on trial to be of little avail against the destructive scrofulous ulceration which constitutes phthisis, still the palliative good which is derived from it, renders it a valuable addition to our list

of remedies; and if the cure of phthisis is to be effected through the strength of the constitution, it will furnish material assistance as a valuable tonic. I shall now make a few observations on the management of the apparatus where iodine is employed. I have had it at constant work for from eight to twelve hours out of the twenty-four. At night, when the patient is settling to sleep, the apparatus is suspended from the roof of the bed; and once arranged, it continues its work quietly and silently for four or five hours, while the patient, in a composed sleep, is all this time inhaling the medicated air. In the morning, for three or four hours before the patient rises, it is again at work; and if necessary, in the mid-day, while the patient reads at a table, or, what is better, reclines on the bed, with the curtains drawn round three of the sides. The rate of evaporation, which generally gives a sufficiently strong impregnation to the air, is, when the tincture of iodine drops from the cotton wick at the rate of from six to eight drops per minute. At this rate about six drachms of the tincture will be evaporated in an hour; and as every particle of the iodine is diffused in watery vapour through the air, there are thus diffused in the minutest state of division through the air, in every hour, about thirty grains of iodine. If we suppose the patient to inhale only one-twentieth of the iodine evaporated, he will inhale in each hour, and apply to the diseased surfaces, one grain and a half of iodine in a state of the most minute division or solution. This quantity we know is quite sufficient to exert a decided action upon scrofulous ulceration; for we find on reference to Lugol's valuable work on the employment of iodine in scrofula, that in external scrofulous ulceration, the preparation of iodine which is found beneficial, is a solution which contains only about three grains of iodine in each pint of fluid. The duration of the inhalation can of course be extended at pleasure.

I may, in conclusion, observe, that since iodine and other agents exert so powerful a control over diseased secretion, and unhealthy ulcerations of other parts, when locally applied, there is at least a warrant for hoping, that when we have the means of fairly bringing the same agents to act locally, and for a sufficient length of time, upon similar

diseased actions in the lungs, we may expect, at least in some instances, similarly gratifying results. The apparatus I have described furnishes us with means of doing this; and I hope at some future time to be able to bring forward a detailed account of the results. I shall esteem myself very fortunate, indeed, if I add ever so little to the means we possess of combating that opprobrium of our art—consumption; and to these, if there be any, who would discourage or reprobate new attempts at cure of this disease, I would say in the words of Beddoes, “When men reprobate new methods, as unjustifiable *experiments*, let them, in the name of common sense and humanity, be asked the following simple questions:—Whether any thing can be more unjustifiable, than perseverance in *experiments* of which constant repetition has rendered the failure certain? Whether, in such a disease, any innovation that does not increase pain and shorten life, can be an object of just apprehension? Whether, after failure, there do not remain to him who employs extraordinary measures, just the same resources as to the adversary of improvement? And, whether the innovator is likely to be so stupid as not to know how to draw the utmost advantage from the saline draught, the chalk mixture, the syrup of poppies, the acid of vitriol, and that whole tribe of palliatives, which, between ourselves, gentle reader, an observant nurse may soon learn to administer to nearly as good purpose as the most specious doctor?”

“Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.”
CICERO.

THE ANATOMY BILL.

ALL great evils, it is said, will at last cure themselves, as a noxious body will irritate the surrounding parts till they take the matter in their own hands, and after a due concoction get rid of the offender. This process is, we hope,

about to be exemplified in the management of the Anatomy Bill. During the late season, in which Providence has preserved the metropolis from more than the average of mortality, the total inefficacy of the Bill, as at present worked, has been fully proved. So great has been the dearth of subjects, that there is scarcely a school in which it has been possible to carry on the anatomical lectures and demonstrations without the interruption of several days, and scarcely a pupil who has been able to pursue his studies in a profitable, much less in a conscientious way, or to exhibit in his examinations that practical experimental knowledge of his subjects which is so essential to his future success. Examiners, teachers, and learners, have alike been distressed and disgusted, and all now seek a remedy for the evil which weighs upon them, and like a heavy incubus impedes their exertions, however anxious they may be to make them.

Meetings of the anatomical teachers have lately been held to consider the subject and cause of their present difficulties; and although the method in which they may be remedied has been far from meeting with unanimity, yet the agreed opinion of all at the very first consultation was (as we have already often said), that a great portion of the evil was due to the present Inspector of Anatomy and Purveyor of bodies. Without preferring the least imputation on either his moral or intellectual character, it is certain that his mode of acting in his official capacity, and his general habits, are the very opposite of those which would be best suited for obtaining a sufficient supply of subjects for dissection. This is a fact in which, however expressed, all connected with him officially, will with more or less of appended disapprobation, cordially agree. We believe, and it is generally allowed, that he distributes

the bodies with no evident partiality for one school rather than another, and that he discharges his sinecure duties as Inspector in a manner which is at least inoffensive to the schools; but as Purveyor, no one will deny that he is totally inefficient, and therefore most mischievous, crippling the exertions of others, and unable or unwilling to supply them by his own. He renders the bill, which would, if well worked, afford ample opportunities for a complete practical study of anatomy by every student, altogether inefficient—makes the facility of learning even less than before the bill passed—and risks a return to the disgusting practices which it was intended to remedy.

The sufficiency of the present legislative enactments, and the inefficiency of their present manager being thus unanimously acknowledged, where is the remedy? Of course no one doubts that it would be in the removal of the bad which mars the good. But this might not be easy; for, independently of the general difficulty in, and distaste for, an attack upon one holding a lucrative government office, the incubus has some important influence. The chief author of the efficient bill is the chief patron of the inefficient manager, and has already often shewn his determination to support him through good and bad report, and under any circumstances. The determination, therefore, which we understand the teachers have now arrived at is, to apply to the Secretary of State, to remove the duties of purveying from Dr. Somerville, and confer them upon some person appointed by themselves, or by the College of Surgeons. He would thus still retain his original office of Inspector of the Schools, with the charge of seeing that the enactments of the bill were obeyed, and the subsequently appended office of Distributor.

The Council of the College of Sur-

geons have declared their readiness to undertake the task of obtaining a sufficient supply of subjects, if the necessary arrangements can be made; and it is most earnestly to be hoped that no difference of opinion among the teachers—no objections falsely founded on a general hostility to all institutions, or a peculiar one to the College—will be allowed to frustrate the good that must result from a change like this, which is now contemplated. We wish that those who, entertaining feelings of hostility to the College, are jealous and afraid of giving it any further power than it now possesses, would fairly weigh and compare the inconveniences which they have already experienced, with those which they imagine may follow. Have they been able (except in the years when some fearful epidemic has been raging) conscientiously to teach their pupils that for which they received their money? Have they been able to supply the opportunities for a practical study of anatomy which they guaranteed, and for which they were paid as much as for their daily lectures? Have the pupils during the past season learned their anatomy by such means, or to such an extent, as will be either creditable to their teachers, or profitable to themselves? In short, have lecturers and demonstrators been able fairly, and to the satisfaction of themselves and their pupils, to fulfil the contracts which they entered into, and by which the pupils were subjected to a heavy expense? Most certainly they have not. The opportunities for studying anatomy have been shamefully deficient; the pupils have paid dearly for that which they have only partially received; and the lecturers have been continually at a loss to obtain materials for their own use. Instead of being stimulated by the abundant supply of occasion, to the thorough learning of this most useful part of their professional pursuits, the students have

had the greatest difficulty in acquiring as much as is necessary for their examinations; and for this they have been obliged to resort to books and pictures, to grinding, and to other things which they ought, and if they could would wish, to spurn. At present, we allow, this has not been the fault of their teachers, for the time was scarcely arrived when their exertions for an improvement could be available; but now, when an opportunity is offered for establishing the subject on better grounds, and for obtaining full or even superabundant opportunities for study, the pupils may justly look to the lecturers to give them a fair return for their entrance-fees, and we cannot imagine on what grounds they can be conscientiously refused.

In place of these evils, which none are better acquainted with than the teachers themselves, for none (except, perhaps, the pupils) have felt them more keenly, what are anticipated by those who would object to the co-operation of the College of Surgeons? We have heard of none; except, indeed, those vague and unmeaning fears which haunt some minds, as if the deeds of public bodies were necessarily dishonest—as if gentlemen and honourable men in private life dismissed all their fairness and their honesty when they act in public. Such as these are the theoretical grounds for the imagined evils; to prevent which, some of the teachers are reluctant to permit a change for certain good from the present shameful state of the case. This, however, is certain—that if they refuse to co-operate in obtaining a better supply of subjects, they will have no right to demand fees from pupils under what will then be the false pretence of teaching them anatomy; and the pupils themselves will then, probably, not delay to apply their own practical remedy, by abandoning the schools from which

such opposition to their interests emanates.

The advantages that would result from the College of Surgeons undertaking to obtain the supply of subjects, are so evident that we can imagine no fears sufficient to authorize any teacher in a reluctance to accept their cordial co-operation. No one will doubt that the numberless sources of supply which are closed, for various reasons, to the influence of Dr. Somerville, will be at once and again opened when solicited by the interest of a number of gentlemen in whom the public place full confidence. When an important public body like the College of Surgeons makes itself (by its Council) responsible for the fulfilment of the enactments of the bill, we shall no longer hear of discontent at the laxity with which evasions of it are permitted, or of the numberless reasons for withholding bodies which are continually urged under the present administration. And in case of grievance or difficulty of any kind (of which one might occur where hundreds now do), we should have the College at once open and accessible, instead of passing through Dr. Somerville to the Home Secretary of State, who will generally care and know as little about anatomy and its study as can easily be conceived. Above all, the whole Council of the College are professionally, and some of them personally, interested in the efficient management of the bill. There is not one who would not be gratified, if not profited, in obtaining a full supply of subjects for every school, and who would not use all his interest for that end; while now the hands of those who are professionally interested are completely tied, and their exertions neutralized by the injudicious and indolent conduct of those who at present hold and misapply the powers of the act, having no other than a pecuniary in-

terest to serve, and being permitted to serve that carelessly and indolently.

The plain and simple end which the teachers ought to keep in view is, to obtain by any fair means an ample or even a superabundant supply of subjects. When they were left to themselves, some succeeded in doing so; but others, from their own faults, failed, and so they quarrelled, and at last unwisely agreed to submit to a self-offered king—the present King Log. Like the monarchical frogs of old, they now all see their error; for if his majesty has as yet crushed but a few to death, he has crippled them all—not one has escaped from injury by the heavy and immoveable weight of their inactive lord. In fact, under Dr. Somerville's monarchy the teachers have been far worse off than under their own republic, when their motto was, "Every one for himself;" then some only were ill supplied—now all are; then anatomy might be fully studied in at least some schools—now it can be learned no where, and London will soon cease to offer any opportunities for the study, except, as in old times, by stealth and dishonesty.

If, therefore, any part of the teachers now choose, from merely political motives, or from unfair and ungrounded apprehensions that their private interests might suffer, to oppose a plan which they themselves allow would remove all the present positive and otherwise insuperable evils, upon them must the blame rest. They have received the offer of co-operation from the College of Surgeons; the whole management will be conducted openly and before their eyes: they know that there is no necessary, obstacle except their own present opposition or reluctant acquiescence; and if London ceases to afford a good anatomical school, it will be their fault, and to them must the pupils look.

WESTMINSTER HOSPITAL.

CLINICAL LECTURE, BY JNO. BURNE, M.D.

Elephantiasis of the Abdomen.—Ecthyma.—Purpura Urticans, with Lithic Acid Diathesis; Alkaline Treatment.

GENTLEMEN,—The French pathologist, Bouillaud, in reviewing the work of M. Alard, "*De l'Inflammation des vaisseaux absorbans lymphatiques, dermoïdes et sous cutanés, maladie désignée par les auteurs sous les différens noms d'éléphantiasis des Arabes, d'œdème dur, de hernie charnue, de maladie glandulaire des Barbades, &c. &c.*"* advanced an opinion that the elephantiasis of the Arabians depends sometimes on an affection of the venous system, rather than of the lymphatic system; and he has since adduced a case in support and illustration. In this case the lower extremities were enormously swollen, and of a lardaceous consistence, and all the veins obstructed by fibrinous coagula.

Both Bouillaud and Alard regard the elephantiasis as analogous, if not identical, with the phlegmasia dolens; the latter attributing it to inflammation of the lymphatics, the former to obliteration of the veins. The near relation between the elephantiasis and the plegmasia dolens, of which last I have so lately spoken, induces me to detail to you the case of elephantiasis of the abdomen which was under my care in the hospital in 1836.

CASE XXX.—*Elephantiasis of the Abdomen.*

Rebecca Carter, aged 52, of full stature and strong frame, was admitted into the hospital on the 19th of July, 1836.

She had been affected for the last two years with an enlargement of the abdomen. Viewed in the erect posture, with her clothes on, she had the appearance of a woman affected with ovarian dropsy; but undressed, the enlargement was found to consist of a pendulous growth of the integuments of the abdomen, reaching to the middle of the thighs. The skin of the front part of this tumor, around and below the navel, was of a dull colour, thickened, hard, and scabrous, and its surface studded with numerous elevations or small tumors of a similar character; laterally towards the hips and inferiorly, the thickening and hardness of the skin were much less, the surface shining and unequal, the inequalities irregularly lozenge-shaped. The dull colour, the thickening, and the rough hard un-

equal surface, resembled very much the elephant's skin.

The tumor, when lifted up, was perfectly moveable on the muscular parietes of the abdomen, was free from pain or tenderness, and weighed probably fifty pounds: it was the weight and dragging from above downwards of which she principally complained.

In the abdomen a tumor was palpable in the region of the spleen, and was probably an enlargement of that viscus.

The patient's general health was not materially impaired; menstruation had continued regular and abundant; and soon after she had been received into the hospital a profuse discharge, similar to the menstrea, commenced from the uterus, and continued unremittingly for five weeks, exhausting her very much. She was directed to take

Ergotæ, gr. x.; Potassæ Sulphatis, gr. v.; Zingiberis, gr. iv. M. twice a day.

To the tumor was applied the Unguentum Iodini Compositum. In addition to the discharge from the uterus, there took place, from time to time, a copious exudation of a straw-coloured fluid from several vesicles which had formed and burst on the lateral surface of the tumor. The exudation would continue several days, and then stop spontaneously; and the same thing, I was informed, had occurred frequently before she came under my care; vesicles to the number of three or four forming spontaneously, then bursting, and discharging to the amount of several pints. This fluid was examined by Dr. Prout, who reported as follows:—"The specific gravity, 1024, being somewhat below the average specific gravity of the blood, which it otherwise much resembled in all respects. In a day or two it deposited spontaneously a considerable quantity of a feculent albuminous matter, after which it remained transparent, and of a greenish colour."

The ergot agreed well, and restrained the too abundant discharge from the uterus; while, at the same time, it promoted the secretion of urine, and was on this account persisted in at the desire of the patient. No good appearing to result from the use of the iodine ointment, it was discontinued.

The repeated discharge of serum from the vesicles reduced on every occasion the volume and weight of the tumor, though the effect was not permanent, the tumor regaining its usual size soon after the discharge had ceased. The temporary diminution of the tumor by the serous discharge suggested the use of acupuncture; and several needles were introduced in the circumference of the tumor, where the

* Archives Générales de Médecine, tom. vi. p. 315.

† Ibid. p. 567.

skin was less changed, and where, on pressure, it pitted like an œdema, though less easily. From these acupunctureæ serum oozed out as freely as from the vesicles, and I now began to entertain hopes of permanently reducing, if not altogether dissipating, the tumor; but here I was disappointed, for, immediately the drain ceased, the tumor again enlarged. Acupuncture was, however, persevered in to a great extent; then puncture by a lancet freely and extensively; yet the pendulous growth could not be reduced beyond a certain volume, while it increased when there was no longer any discharge.

This process having been carried into full effect for several weeks, and the patient despairing of obtaining any permanent benefit, declined to submit to it further, as also she did to other measures, except the ergot. She was now transferred to the incurable ward, where, after some months, her legs began to swell, and attained an enormous size; she became universally dropsical, and expired.

The death of this patient occurred in the autumn, while I was out of town, and I am unable, therefore, to give you any account of the appearances on dissection.

Seeing the analogy—even relation—between this tumor, the Barbadoes leg (elephantiasis), and phlegmasia dolens, the last of which is now known to depend on obliteration of the veins, and the elephantiasis or Barbadoes leg suspected by Bouillaud to depend on the same cause (venous obstruction), it would have been interesting to investigate the venous system, not merely as connected with the elephantiasis growth of the abdominal integuments, but with the œdema of the legs and universal dropsy. I have presented to you this case, not with a view either to support or disprove the opinion of Bouillaud, but on account of its rare occurrence, and its similarity in general features to the extremities affected with elephantiasis and phlegmasia dolens.

You may remember to have heard or read accounts of the celebrated case of elephantiasis of the scrotum, in Hoo-Loo, the Chinese, who came over to this country to have the tumor removed. I saw this case many times, and the resemblance between it and the pendulous growth of the abdominal integuments, which I have described, was exact. The disease in the Chinese was seated in the scrotal integuments, and had attained an enormous size, as large, I think, as an eighteen-inch globe, and was removed by a very distinguished operator, Mr. Key, at Guy's Hospital. I conversed with Mr. Key on this subject a few days back, but he had no reason to suppose obliteration of veins to exist in, or to have been the cause of,

the tumor; on the contrary, there was great venous hæmorrhage during the operation.

CASE XXXI.—*Ecthyma Vulgare*.

Elizabeth Storey, age 20, admitted into the hospital on the 30th of October, 1838, affected with an eruption for two months past. The eruption, chiefly seated on the lower extremities, was pustular, distinct, and covered with scabs nearly the size of a pea, the base being irregularly round, sore, and inflamed. She said the eruption commenced with small, itching, red, hard pimples or pustules, which in two or three days inflamed more, enlarged and contained matter at the top or apex; that the pustules then burst, and scabs formed, which after a short time fell off; that others occurred in succession, and some had appeared on her arms.

She was short in stature, had a pale conjunctive membrane, a full face with a flushed cheek, was plump, though flabby, and complained of weakness, head-ache, and loss of appetite. Her bowels were usually confined, and menstruation irregular and abundant. She had a white tongue, with a pulse rather frequent, but no fever.

This was a very well-defined case of *ecthyma vulgare*—the mildest form of *ecthyma*. The *ecthyma* is the third species of the order *Pustulæ* of Willan, and is characterized accordingly by the early formation of pus at the apex of the eruption; also by the eruption leaving a hard inflamed base, and the pustules being distinct and not very numerous.

Besides the eruption, the health of this girl was weak, and the digestive organs disordered, the usual accompaniments of *ecthyma*. I therefore adopted a plan of treatment calculated to regulate the bowels and improve the general health.

R Pil. Hydrarg. gr. i.; Pulv. Rhei. gr. iii. F. pil. bis quotidie.

R Decocti Cinchonæ, ℥j.; Sodæ Sesquicarb. gr. v. M. bis quotidie.

She complained that these medicines did not agree, on which account the bark and soda were omitted, as also, in two days more, were the rhubarb and blue pill. Other medicines having the same object in view were prescribed, but objections were also taken to these. Instead of medicine, therefore, I gave her four ounces of wine daily, and regulated the bowels by a compound rhubarb pill: under which plan she soon recovered, and left the hospital. The eruption left no marks behind.

CASE XXXII.—*Purpura Urticans*.—*Lithic Acid Diathesis*; *Alkaline Treatment*.

A boy, eight years of age, of plethoric

habit, sanguine temperament, and of a decided lithic acid diathesis, being subject frequently, and on the slightest irregularity in diet, to a deposit of lithic acid in the urine, like red gravel or sand, became affected with a slight sore throat, headache, and feverishness, in the beginning of September, 1838. The throat got well in a few days, heaviness of the head only remaining. At this time he struck his knee against a table, and three days afterwards rubbed it against a wall accidentally. On the following day, the 12th of September, the knee had become very much swollen, red and hot all around, particularly on either side of the ligament of the patella: fever attended.

Four leeches were applied to the knee, an alterative powder was given at night, and an aperient in the morning.

13th.—The leeches bled freely for an hour into a poultice; two then ceased; the two other bled through the day till the evening, when one stopped; the fourth continued to bleed all night, and was stopped with difficulty. I think the boy must have lost six or seven ounces of blood, which took the colour from his cheeks. The swelling of the knee subsided rapidly afterwards; but other swellings, red, tender, painful, and seated apparently in the adipose tissue, arose on the thumb, on the back, and other parts, most suddenly.

On the 14th, some red spots were perceived on his body; and on the 15th, in the morning, an extensive eruption on his legs and thighs, of the purpura character, well marked. The spots were purplish red, elevated, circumscribed, and of various sizes, from one to six or seven lines in diameter—some circular, some oval; and on the calves of the legs were one or two stripes or wheals several inches long. He complained of stiffness of the limbs generally. There was no sponginess of gums.

Capt. Pulv. Jalapæ, gr. x. mane quotidie, et Potass. Bicarb. gr. v. bis quotidie.

In the course of two days the elevated spots subsided nearly to the level of the skin, their colour becoming purple; then, about the fifth day, brown; and later, yellow, and diffused, like an ecchymosis from a contusion. The feet were œdematous; and now, again, several red, tender, and painful swellings formed suddenly, one of them occupying the scrotum, and extending along the course of the urethra, the swelling seeming to be rather under than in the skin—like nettle-rash under the skin.

The jalap acted mildly, but the dejections being offensive, a scruple dose was administered in lieu of ten grains; this purged him briskly, with great relief to

the pains and stiffness of the limbs, and improvement in the character of the evacuations. Finally, a hot bath dissipated all remaining pain, and, with change of air, established perfect convalescence.

This case was a well-marked example of Purpura Urticans, the distinguishing peculiarity of which is the elevated nature of the eruption above the ordinary level of the skin. The occurrence of such a disease in such a constitution was unexpected; and although much blood had been lost by the leeches, one could not entertain the idea of general debility, and, consequently, not think of adopting a tonic treatment. The generous diet, wine, bark, and acids, recommended by Dr. Willan, are very properly questioned by Bateman, and their inapplicability in many cases pointed out. The very acid state of the urine in the case under consideration, and the lithic acid diathesis of the little patient, which was well known to me, opposed also the use of acids, and determined me to administer the alkali.

The supposed relation of purpura to scurvy is the reason why an acid treatment, efficacious in scurvy, has been adopted in purpura, and, as it begins to appear, erroneously. In the present instance, an acid treatment was contraindicated by the lithic acid diathesis, and harm would probably have resulted from its use. A friend of mine, subject to purpura, derived no benefit from the customary treatment, but got well rapidly under the use of the liquor potassæ.

Purging, as recommended by Dr. Harty, of Dublin, is a most essential part of the treatment, and was particularly beneficial in the case before us, where the scruple dose of jalap, which purged briskly, was followed by immediate amendment. No purge can be better than jalap and calomel.

It is remarkable that not only on the present occasion, but on several others when leeches were applied to this boy, some of them bled most obstinately. It was always a difficult matter to arrest the bleeding of leech-bites in him; shewing thus a hæmorrhagic disposition associated with the purpura.

The continued bleeding from leech-bites in children is often not only troublesome but pernicious, very much more blood oozing away than is desired—to an extent sometimes as to endanger life. The same inconvenience and mischief will happen occasionally from leech-bites in the adult. On this account I make it an invariable practice to direct that the bleeding should be stopped in *one hour* after the leeches have detached themselves,—which I find a safe rule. The bleeding will, however, often persist in spite of or-

dinary endeavours to stop it, and you are called for this purpose. I have tried a great many means, as pressure, a solution of alum, or of nitrate of silver; but I find none so efficacious as a pencil of nitrate of silver pointed and inserted for a moment into the leech-wound. This has never failed in my experience.

ROYAL INSTITUTION.

March 7th, 1839.

Professor Grant on the Motor Powers of Reptiles.

THIS day the Fullerian Professor of Physiology delivered before a select audience an entertaining lecture on the motor functions of reptiles. As the peculiar character of the motor apparatus in each class of the animal kingdom is dependent upon the nature of the circulation, Dr. Grant first demonstrated the anatomy of the heart proper to this extensive class. In fishes there is but one auricle and one ventricle, the venous blood being collected in the auricle and thence transmitted to the ventricle. From the ventricle it goes to the bulbus arteriosus, which gives off the branchial arteries. Hence it returns arterialized by the branchial veins which unite and form the aorta, by the contractile force of which the blood is distributed through the body of the animal. In reptiles there are two auricles and one ventricle, partially divided into two chambers. The consequence is, that the venous and the arterialized blood are, to a certain extent, intermixed. From the right chamber of the ventricle, the left aortic trunk and the left pulmonary artery generally arise; from the left chamber the right aortic trunk and the right pulmonary artery. It is from the right aortic trunk that the arteries of the head and upper extremities take their origin; and these parts, as in the fœtus of mammalia and birds, receive a larger proportion of arterial blood. The right and left aortic trunks unite posteriorly to form the descending aorta.

Dr. Grant gave a minute description of the structure of the amphibia, and of the interesting metamorphosis of the branchial into the pulmonary circulation, which occurs in these animals. He illustrated this part of his subject with a profusion of diagrams, in which every order of amphibia was represented.

The branchial circulation in the *Rana esculenta*, during the earliest period of its larval condition, when it has external branchiæ, is similar to that of the other batrachian reptiles. The arterial trunk

divides immediately into several aortic arches on each side, corresponding to the branchial arteries, which give off anastomosing branches to the branchial veins. During the second period, in which the frog has internal covered branchiæ, and in which the lungs are being more and more developed, the distribution of the vessels is more like that of fishes. In the larva of the frog, however, there is a short anastomosing branch connecting the artery and vein at the commencement of each branchial arch, which does not exist in the fish. After the metamorphosis, there remains on each side but one arterial arch, which unites with the one of the opposite side to form the aorta abdominalis. The bulbus arteriosus divides into two diverging stems, each of which consists of three trunks united, and of which the cavities are separated by thin septa. These are the remains of the branchial arteries which have united to form apparently one stem. The middle of these arteries is continuous with the aorta; the inferior gives off the pulmonary artery, whilst the superior forms the trunk which supplies the head. The pulmonary artery, in the early stage of the larva, is seen to be very small when passing into the rudimentary lungs; but as these organs enlarge during the transfiguration of the animal, the artery grows larger also.

The true reptiles never possess branchiæ, and undergo metamorphosis only during the fœtal state like the other vertebrata.

The change which the batrachian reptiles experience is not confined to the respiratory and circulatory apparatus; every tissue suffers a corresponding modification. In the mutation of the tadpole, not merely are its lungs rendered fit to extract oxygen from the atmosphere, but its skeleton is totally altered. Whilst in the water, its motions are obviously of an awkward temporary character, unlike those of the fishes, the permanent denizens of that medium. The coccygeal vertebræ of the tadpole are atrophied, and become absorbed into the system of the animal. The form of each remaining vertebra is changed; from concavo-concave it becomes concavo-convex. The intimate structure of the bones grows dense, and better fitted to resist the energetic action of more highly oxygenated muscles. In the frog, nine vertebræ alone remain; but a large pelvic arch is attached to the vertebral column, and extensive motion is permitted by means of two strong ilio-sacral articulations, thus adapting it to the saltatory progression proper to its new position, and suiting it to the search of more highly-organized food.

The mixture of the arterial and venous blood occasions a lower temperature in

reptiles, and adapts them for the circumstances in which they are destined to act, *e. g.* to lie dormant for weeks and months in the mud of rivers. The cellular structure of the outer covering, too, is a particular provision adapted to this contingency of their life, by supplying a certain degree of oxygenation to the blood.

The character of the irritability developed in the muscles is modified by the mixture of the blood, instead of the vivid and rapidly evanescent mobility of the mammalia. The motion of the reptile is slow, but pertinacious, enabling it to contend, with advantage, in its own element, with its enemies, or its occasionally powerful prey. The form of the lungs in these creatures, no less than that of the heart, indicates the imperfect arterialization of the blood. The pulmonary cells are large, and dense in texture, so that the air is not, as in mammalia, minutely divided, in order that it may be brought into contact with a larger surface of the rete mirabile.

Dr. Grant now demonstrated, in the most perspicuous manner, the difference of texture exhibited in the muscles and bones of fishes, reptiles, and mammalia, in which he made evident the gradual improvement in quality of these structures, from the fish to the higher quadruped. The warm-blooded muscle of the latter supplied a striking contrast to the pallid muscle of the former; but the texture of the bones and the arrangement of sutures formed still more remarkable diversities, and proved how admirably contrived were the properties of each for the respective media in which they were destined to live and propagate their kind.

Dr. Grant entered successively into a consideration of the osteology and myology of the Batrachian, Saurian, Ophidian, and Chilonian reptiles, and the modification of functions which the variety of structure, evident in these apparatuses, produce.

The motor apparatus of fishes, he said, is adapted to the dense medium in which they move; the fins, which form the upper and lower extremities of this class, are unattached to the spine. This is also the case in the fossil Ichthyosaurus. But in the reptile tribe we discover the sacrum and scapula, contrivances which are fitted for progression in a rarer medium. In the amphibious animals the bones contain most animal matter, are soft and flexible, are most detached from each other, and moveable, have their elements most disunited, and the whole skeleton is least perfect and most fish-like in its form. This is seen in the anguilliform bodies of the proteus, the siren, and the amphiuma,

where the skeleton consists of a vertebral column almost without extremities (and what use had they for more in the water?) The intermediate creeping tadpole forms of the axoloh, the menobranchus, and the triton, where the legs and arms are further developed, have their coccygeal vertebræ much developed for their progression through the water. Those which leave the water and their water-breathing organs to assume a terrestrial life as the frogs, toads, and salamanders, have their extremities more developed to support the trunk in the thin medium of air, and have their vertebral column the most remote in its general form, and in the structure of the separate elements of each vertebra, from that of fishes. Indeed, these skeletons almost rival the anatomy of the lizard forms of sauria, especially in the round-tailed land-salamanders, which pass through their larval state in the body of the parent.

In the ophidian reptiles we have a class of animals destitute of anterior and posterior extremities, yet capable of a great variety of those active movements which we see in animals the most gifted with those parts. We see them as if running on all fours, pursuing their prey, rapidly winding through the grass, and through the low vegetation that covers extensive plains. If the prey, to escape from danger, should betake itself to trees, and imagine itself there to be in safety, we find these animals winding like an ivy-branch round the tree, and almost without apparent motion of any portion of their trunk, gliding till within reach, and then, with the velocity of a spring let loose, they dart forward and twine round their prey. If the prey should rise from the ground into the air, we see these serpents, as if they were gifted with wings, spring with velocity from the ground, dart upon the bird, and seize it. If the animal be a quadruped, and plunge for safety into the water, the serpents still pursue it in that element, swimming like fishes. The skeleton of these agile animals consists merely of a vertebral column and ribs. The vertebral column here composes almost the entire skeleton, for the ribs are only prolongations of the transverse processes—a vertebral column pliant like a cord in all directions, but solid in each particular bone, to give attachment to powerful muscles, which conduce to the strength and velocity of all the motions of the animal. This strong and flexible column consists of a greater number of vertebræ than is to be found in any other of the vertebrata, thus forming a striking contrast with many of the batrachian reptiles. The vertebræ of serpents are curtailed of all long project-

ing processes, and approach more nearly than those of other vertebrated animals to the form of the simple cube.

In the entire structure of these animals there is a beautiful adaptation to the living exigencies of their situation. The vertebral bodies terminate before by a deep, smooth, concave, articular surface, with sharp margins lined with cartilage, and lubricated with synovia. The bodies of the vertebræ terminate behind in a very regular, oblique, smooth, hemispherical eminence. These meeting together are locked into each other, and secured by a strong capsular ligament. Thus a secure and extensively moveable articulation is formed. On the sides of the vertebræ the base of the transverse process only is preserved, and that terminates in a *convex*, smooth, articular surface, upon which plays the *concave* articular surface of each rib. Thus the ribs of serpents are the transverse processes developed, but detached at their base by a freely moveable articulation.

The saurian reptiles have a more highly developed skeleton than the serpents. They have a complex sternum and scapular apparatus, a pelvic arch, together with allantal and sacral extremities to raise the serpent's trunk from the ground. The inferior grade of development of these animals, as compared with the mammalia, is indicated by the coarse fibrous texture of the bones. Even in most of the long bones of the extremities, the cancellated structure occupies the whole extent.

The Professor now gave a most minute demonstration of the varieties of structure in the substance of the bones, and in the form of the different articulations, displayed by the various genera of the saurian reptiles. He then dwelt upon the diversities of their motor functions with a characteristic enthusiasm, which, in spite of a somewhat monotonous delivery, renders the prelections of this gentleman highly attractive. He also amplified upon the peculiarities of the Indian ganial, the Nilotic crocodile, and the alligator of the Amazon.

The learned professor was equally diffuse upon the structure and functions of the Chilonian reptiles, remarkable from their feeding for the most part on vegetable food—a character of rare occurrence in the class of reptiles. From their small respiration, and having but one ventricle of the heart, their movements are languid. Whether creeping among the low vegetables, or lying torpid in their burrows, these animals are constantly exposed to the trampling of heavy quadrupeds; and their strong, arched skeleton, covering both the viscera and the muscles, affords them se-

curity from dangers which they have not acuteness to perceive, nor activity to shun. We regret we have not space to follow Dr. Grant in his beautiful description of the anatomy of the motor organs of these reptiles, whose humble vitality survives the casualties of a thousand years.

IMIOS.

WESTMINSTER MEDICAL SOCIETY.

Saturday, March 30, 1839.

W. D. CHOWNE, Esq. M.D. PRESIDENT.

Fracture of the Neck of the Femur.—Discussion on the Poisonous Effects of Carbonic Acid.

DR. BROOKE exhibited the head, neck, and the upper fifth of the shaft of a femur, which he had taken on that day from the body of an old woman, between 70 and 80 years of age. The accident, which produced fracture of the cervix, occurred three years ago. Dr. Brooke was called in, and found the patient suffering excruciating pain. The limb was shortened and everted. He placed the woman on a "fracture-bed," and she experienced immediate relief. In about three months she abandoned this apparatus, and she was able to walk, with the assistance of a crutch, for the remainder of her life. The permanent curtailment of the limb amounted to three-fourths of an inch. In the preparation, the neck of the femur was shown to be totally absorbed, and its place supplied by a thick and strong ligament, resembling, both in shape and bulk, the original bony cervix. Its pliability was the cause of the limb being shortened when the patient rested her weight upon it.

At nine o'clock, the President called upon Mr. Snow, as the mover of an adjournment on the previous evening, to proceed with the discussion of Dr. Golding Bird's doctrines regarding the mode in which death is produced by carbonic acid: that gentleman consequently rose, and stated, that the excellent address of Dr. Bird had induced him to modify his opinion as to the *modus operandi* of charcoal fumes. He had formerly entertained the idea that carbonic acid, like hydrogen and nitrogen, produced death simply by the exclusion of oxygen; but the experiments of Dr. Bird and Collard de Martine had convinced him of the contrary, especially that particular experiment in which 79 parts of oxygen, being mixed with 21 parts of carbonic acid, and an animal being immersed in this atmosphere, speedy death was the consequence. He (Mr. Snow) had instituted several experiments as tests of those of Dr. Bird and M. Col-

lard, and he was bound to say that the results were confirmatory of the accuracy of their conclusions. He admitted, therefore, that carbonic acid did not kill by excluding oxygen merely; but he was loth to believe that this gas acted specifically as a poison, as lead or arsenic did. It still appeared to him that its effects were of a negative or indirect character. There existed some circumstances in the experiments of Dr. Bird and M. Collard, which, in his opinion, tended in some degree to vitiate the results. M. Collard's descent, for example, into the fermenting vat, in which he was immersed in a medium of carbonic acid, and breathed through a long tube communicating with the air outside the vat, was rendered inconclusive by the fact, that, from the length of the tube, he must necessarily have inhaled an impure atmosphere; for half the air contained in the tube would consist of what he had expired, and would be consequently, to a certain extent, deoxygenized. In this way the air he breathed would be rendered less and less pure, and the apoplectic symptoms which occurred might have been produced without supposing any effect to arise on the skin from the circumambient carbonic acid gas. Another circumstance which detracted from the conclusiveness of Messrs. Bird and Collard's experiments, was the small size of the vessels which they had used for insulating the atmospheres in which they had placed their animals; for the respiration of these creatures alone in so confined an atmosphere of even pure air would so corrupt it as speedily to produce asphyxia. In his experiments he (Mr. Snow) had used a vessel containing 2000 cubic inches of capacity—a space in which the kind of animals he employed could live a long time without inconvenience, and in which, consequently, it was necessary to allow very little for the corruption of the atmosphere by the animals' breathing. The animals he employed were small birds, such as sparrows and linnetts, and white mice. He employed various mixtures of gases. He first used a mixture of 75 atmospheric air, 20 carbonic acid, and 4 oxygen. In this medium the birds died in about twenty minutes. The white mouse, being removed shortly, was only a good deal distressed in its respiration, and finally recovered. Mr. Snow next mixed the gases in the proportion of 85 atmospheric air, 12 carbonic acid, and 3 oxygen. The effects upon the animals were the same in kind, but the time occupied was greater. The breathing became distressed in a few minutes; the inspirations were much deeper, and became more and more accelerated and laborious until the death of the animal. Mr. Snow made

a third mixture, in which the proportions were, 90 atmospheric air, 8 carbonic acid, and 2 oxygen. Here for some short time the animals were apparently unaffected, but the fatal train of symptoms soon set in. After this, Mr. Snow made a series of mixtures, in which the oxygen was excluded, and in which the proportions of carbonic acid to the atmospheric air were successively 10 per cent., 5 per cent., 3 per cent. In all these instances, the fatal effects upon the immersed animals were much more rapid than when the oxygen was added.

Mr. Snow now detailed another series of experiments performed by himself, in which the atmospheric air was deprived of portions of the oxygen, by the admixture of nitric oxide. In atmospheres thus vitiated, the animals immersed were after a time affected with dyspnoea, and if unremoved, death ultimately ensued. If small volumes of carbonic acid were added to an atmosphere thus deprived of a portion of its oxygen, its deleteriousness would be augmented, of course. Thus it appeared, summarily, that Mr. Snow had experimented on the effects upon animal life produced by the following respiratory media:—1. Simple atmospheric air; 2. Atmospheric air and carbonic acid, with a due proportion of oxygen; 3. Atmospheric air and carbonic acid, without a due proportion of oxygen; 4. Atmospheric air deprived of a proportion of its oxygen; 5. Atmospheric air thus deprived of its oxygen, and mixed with carbonic acid. From a careful consideration of all the facts, Mr. Snow came to one or two conclusions. He inferred that the presence of oxygen acts in some degree as an antidote to the influence of the carbonic acid; that proportions of carbonic acid not producing apparent effects on the first immersed of the animals, ultimately prove fatal; that carbonic acid does not act as a direct sedative, but effects the destruction of the animal by acting as a perpetual excito-motory stimulus upon the mucous membrane of the air-cells, according to the theory of Dr. Marshall Hall, and that death occurs from exhaustion of the nervous power.

Mr. Snow further observed, that Dr. Christison had shown that death might be produced in an atmosphere which supported the flame of a candle. The flame of a candle could not be supported in an atmosphere containing 4 per cent. of carbonic acid; *à fortiori*, such an atmosphere could not support life. Two eminent chemists, however, had recently stated that they had detected in air, collected from the crowded pit of a theatre, 4 per cent. of carbonic acid, and by which the audience had not been affected. The state-

ments of these eminent chemists were at issue with the facts afforded by experiment, for flame would be extinguished by an atmosphere corrupted with 1 per cent. of this gas. But this effect had not occurred in the theatre; and though it might be said that exhilaration might counteract the effect of the gas upon the human constitution, it could not be said to produce such an effect upon the lights. He, Mr. Snow, could not concur with Dr. Bird in opinion that the head was primarily affected by the carbonic acid. The cerebral symptoms, he thought, were the consequence of the disturbed respiration. In the birds which had perished in his experiments, the brain was not at all affected; there was neither effusion nor congestion.

Dr. A. T. Thomson said that, in order to convince himself of the sedative nature of carbonic acid gas, he had some years since performed an experiment upon his own person. He burnt his hand with sealing-wax. The hand became very painful. He then immersed it in a vessel filled with carbonic acid, and the pain instantly ceased; he took his hand out again, and the pain returned. He now immersed it in a vessel of nitrogen; the pain was not diminished; but replacing it in the carbonic acid, the pain was directly alleviated. From this experiment he (Dr. T.) inferred that the carbonic acid gas did not act simply by excluding oxygen, but that it was a sedative poison.

Mr. Streeter pronounced a severe critical diatribe against the two "eminent chemists" who had presumed to obtrude themselves into the domains of physiology. The mere chemist, he said, was not authorized to pronounce an opinion on any physiological subject; yet two gentlemen of high character in their subordinate science had given certificates, against the authority of the first medical men, declaring the innocuousness of certain "patent stoves." These certificates had, unfortunately, had great weight with the public, and in consequence of that, these pestilent inventions had been permitted most extensively to injure the public health.

Dr. Bird made a brief and lucid reply, in which he expressed his gratification that all the speakers had concurred with him in the most essential points of his arguments. The experiments of Mr. Snow corroborated his own and those of Collard de Martine. The facts elicited went to prove incontrovertibly that carbonic acid gas, inhaled in such quantities as to be enabled to pass the glottis, proved directly injurious to life, and was a deadly poison. In this point of view, the difference between him (Dr. Bird) and Mr. Snow was more nominal than real. Mr. Snow ad-

mitted that the gas was deleterious; and it mattered not to him in what degree it was poisonous, or whether it was so directly or indirectly; it was sufficient that it was granted that it destroyed life in small doses. In his opinion, however, it was as decided a narcotic as opium. He had never seen or heard of a case of poisoning by carbonic acid gas in which symptoms of congestion or inflammation of the brain did not exist. The case of the animals destroyed by Mr. Snow was not in point; for in them the brain was too small in proportion to the entire body of the animal to shew any marks of cerebral action. With regard to the effect of carbonic acid on the blood, he had made a most careful collection of all the authorities on the subject, and published them in a long article contained in the forthcoming number of the *Guy's Hospital Reports*.

Upon the motion of Mr. Clarke, the thanks of the Society were voted to Dr. Bird for his able communication.

IDIOS.

TREATMENT OF PHTHISIS WITH HYDROCYANIC ACID.

M. FANTONETTI, professor of clinical medicine at Pavia, has lately published some new remarks on the treatment of pulmonary phthisis by this remedy. Among others, there were three cases, in two of which there was confirmed phthisis, with an excavation, pectoriloquy, &c. where the hydrocyanic acid effected a complete cure.

These results are too wonderful for us to believe, unless confirmed; and we therefore wish our brethren cautiously to try this method, which has been already employed by several authors, and which M. Fantonetti (with an enthusiasm that perhaps savours a little too much of the south,) says that he uses, with unobscured success, in affections of a totally different kind. The dose given by M. Fantonetti is from 3 to 6, 8, 12, or 14 drops.

It is unnecessary to add, that Gay-Lussac's medicinal Prussic acid is to be preferred, which is diluted with six times its weight of distilled water. The bottle must be wrapped up in coloured paper to prevent the decomposition of the acid by light; and it should be shaken before using, as the acid is very volatile, and not very soluble in water. To counteract the eructations, the coughing, and the irritation of the throat which it causes, the patient may keep balls of gum in his mouth.—*Gazette des Hôpitaux*, Feb. 19, 1839.

[It is clear that the doses recommended are far too large, as appears, indeed, from the effects they are supposed to produce.—*Translator*.]

ANATOMY OF NERVOUS GANGLIA.

M. FAESEBECK, of Brunswick, gives the following account of the results of some minute dissections which he has made of the nerves of the head, and especially of the ganglia:—

1. The *supra-maxillary* ganglion, as first described by Bochdalek, is situated between the bony plates which constitute the facial surface of the superior maxillary bone*, and in the neighbourhood and on the upper side of the roots of the incisor teeth; it forms a long compressed knot, in which the superior, anterior, middle, and posterior dental branches of the second branch of the trifacial nerve unite. It gives off—1. Twigs to the incisor teeth; 2. Communicating twigs to the naso-palatine ganglion; 3. Twigs to the mucous membrane of the nasal cavity; 4. One branch to the nerves of the face.

2. The *naso-palatine* ganglion is formed by the two naso-palatine nerves, while they pass through the foramen incisivum, entering into union with twigs from the supra maxillary ganglion and spheno-palatine nerves. This ganglion distributes twigs to the gums. M. Faesebeck is perfectly satisfied as to the existence of the ganglion in question; but Prof. Müller remarks that its ganglionic nature has not as yet been demonstrated.

3. The *temporal* ganglion is placed at the point where the external carotid divides into the temporal and internal maxillary branches, and perhaps rather to the inner side of the last: it is formed by branches of the sympathetic facial, and superficial temporal auricular nerves, and distributes several twigs to the parotid gland, and to the temporal, transverse facial, and internal maxillary arteries. The superficial temporal auricular never gives branches to the external auditory meatus and to the articulation of the under jaw. Prof. Müller hints that this ganglion may be perhaps only a ganglionic plexus.

4. M. Faesebeck has in three cases found a second ophthalmic or ciliary ganglion on the inside of the optic nerve: and in one case he observed the ganglion to be very small, although the motor oculi gave off five ciliary nerves.

The long root of the ciliary ganglion is united with a branch of the motor oculi, and then the two enter together the superior rectus muscle of the eye. Further, there arise twigs from the naso-ciliary nerve, which are distributed to the levator palpebræ superior.—*Müller's Archiv.*

* M. Faesebeck probably means in the cellular structure of the bone.—TRANSLATOR.

BOOKS RECEIVED FOR REVIEW.

A Short Treatise on Typhus Fever. By G. L. Roupell, M.D. Physician to St. Bartholomew's Hospital, &c.

The Naturalist; illustrative of the Animal, Vegetable, and Mineral Kingdoms; with beautiful Engravings on India paper. Edited by Neville Wood, Esq., late Joint-Editor of "The Analyst," Author of "British Song Birds," the "Ornithologist's Text-Book," &c. &c. Vol. IV., No. XXXIX. Published monthly. Whitaker and Co.

A Series of Anatomical Plates. Edited by James Quain, M.D. and W. J. Erasmus Wilson. Fasciculi LXVIII. and LXIX.—Nerves. Taylor and Walton, Upper Gower Street.

LECTURES
ON THE
CHEMICAL HISTORY, PATHOLOGY, AND
MEDICAL TREATMENT
OF
CALCULUS,
AND THE VARIOUS DISORDERS OF THE
URINARY SYSTEM.

By DR. VENABLES.

Diuresis saccharina.

THE following table is constructed with the view of presenting, in juxtaposition, the principal properties of the urine at different periods, so as that they may be readily contrasted. The properties are divided into sensible, mechanical, and chemical, arranged under the proper titles. In stating the chemical properties, I only notice those peculiar to diabetic urine, although it is evident that the table might be readily enlarged so as to suit more general purposes. In the column of dates I have arranged according as the specimen was, either that of the morning, the noon, or the evening, these times being indicated by the numbers, 1, 2, 3, the first indicating morning urine, the second the noon, and the third the evening.

From the table it will be seen that the presence even of sugar may be masked by the predominance of urea; and it also appears that these two principles alternate with each other, and seldom or never co-exist in large quantity in the same urine, but as the quantity of the one increases, that of the other diminishes. The cases, too, which I have just related, shew that a saccharine condition of the urine may exist without any marked diuresis, and consequently the nature of such cases may be

readily misunderstood. Indeed, until I pointed out to this gentleman the condition of the urine, he was not at all aware of it, and was indulging in a very improper remedy, under his condition of health—namely, mercury, for a supposed torpor of the liver.

It therefore becomes an object of great moment to decide what is the condition of the urine. One of the best guides is, perhaps, the specific gravity. If this steadily exceed 1.030, we may rest almost assured of a saccharine state of the urine, or that there is a tendency so far this way, that sooner or later it will manifest itself. When we add to the specific gravity the sensible properties, especially the colour—greenish or straw-coloured—there is quite sufficient to warrant us in looking upon the case as of the description already noted.

A speedy and certain mode of determining the presence of sugar in the urine is very desirable, and several modes have been proposed for this purpose, but there are none of them certain. Excess of urea is very readily determinable by nitric acid, as you have already seen; and a similarly expeditious method for determining the presence of sugar is desirable. The capability of fermenting by the addition of yeast, is not only uncertain, but is almost as tedious as evolving the sugar by any one of the processes previously detailed. Dr. Runge has proposed a process which he states to be both extremely delicate and no less certain, but the same plan occurred to me long since; and I found, upon trial, that it was neither certain nor delicate. It is founded upon the strong attraction which sulphuric acid has for water, or even the elements of water. His plan consists in evaporating the suspected urine, at a very moderate temperature, to dryness, and then dropping upon the residue, in a porcelain dish or plate, sulphuric acid, diluted with six or eight

parts of water: if sugar be present, it occasions a dark colour, or even a black. This change depends upon the affinity which sulphuric acid has for water, and which, in fact, disposes the elements of this principle, existing in the composition of sugar, to unite and form water, leaving the other constituent free. Sugar consists of oxygen and hydrogen, in the relative proportions for forming water and carbon*. The oxygen and hydrogen unite and form water, and is attracted by the sulphuric acid, and the carbon deserted is left free, and causes the black colour. Here you have an opportunity of seeing the effect of sulphuric acid upon this sugar, and you see it is charred, owing to the liberation of the carbon. But it must be recollected that many other organic principles are similarly affected by sulphuric acid, or undergo charring, as it is designated, by the liberation of their charcoal. Urine contains a number of organic principles capable of being similarly affected. Runge states that his test is capable of detecting one part of sugar in solution in one or even two thousand parts of water or urine. I am at a loss to conceive how such a statement could have been made. The author certainly could never have taken the trouble to examine the validity of this test under the various modifications, otherwise he would have perceived that it was objectionable, from its liability to fallacy, in consequence of the general presence of organic matters in urine. Here you see a solution of five grains of sugar in eight drachms or four hundred and eighty grains of water, which is nearly in the ratio of 1 : 100 instead of two thousand; and you will see, on evaporating to dryness both a drop of the saccharine solution and a drop of urine which contains no sugar, and adding a drop of the diluted acid to each, and exposing to a moderate temperature, if you observe the changes, you see the urinary spot darkens, as you see in this case, much sooner than the actual sugar. Urea and mucus, and, indeed, a number of the organic or animal principles with which urine is almost invariably loaded, will render this test so far fallacious. In a word, it cannot be depended upon†. We must, therefore, depend upon the colour,

smell, and other sensible characters, and the specific gravity; and if these or any other circumstances render the presence of sugar probable, then we must determine that fact by an unequivocal experiment; for the fact is one, unquestionably, of importance, because we shall thus become acquainted with the peculiar diathesis, and avoid medicines, especially mercury, which is highly pernicious in such cases. To sum up, therefore, a pale straw or greenish colour, with a specific gravity steadily above 1.030, render the occasional presence of sugar highly probable. If to these we add a smell of newly-mown hay, and a neutral taste, there can be little doubt; but under such circumstances, however questionable, it will be right to investigate and clear up the point by a special analysis*.

Morbid anatomy.—The morbid anatomy of a disease comprehends the nature of those morbid changes which the tissues undergo during its progress. Were we to confine our notions or inquiries to the actual alterations presented at the time of

water, I think the urine darkens much more quickly, and is ultimately darker. Alcohol, too, and spirituous mixtures, undergo the same changes as a solution of sugar, whether the alcohol be evaporated or not.

* It has lately occurred to me, that Runge's test—namely, the sulphuric acid—by some little modification might be rendered available as a trial test, if not altogether a good indication of the presence of sugar. The great difficulty, according to the present mode of applying the sulphuric acid, is, that the organic matters found in the urine are liable to char or blacken the acid. If the urine be freed from those, the test may then be made available. The method I have lately adopted is this:—A solution of acetate of lead is to be added to the urine; or acetate of lead may be agitated with it. This will coagulate and precipitate the animal matter, which is separated by filtration. A current of hydrosulphuric acid gas is passed through the filtered urine, to separate the excess of lead, and it is again filtered. A drop of the purified and filtered fluid evaporated to dryness indicates the presence of sugar on being treated with diluted sulphuric acid, by becoming black on being evaporated to dryness at a very moderate temperature. If it contain no sugar, the acid either strikes no colour or gives only a very slight tinge of a dusky or tawny hue. I find that half a grain of sugar dissolved in five and even six ounces of urine thus purified, may have the presence of sugar indicated by treating a single drop with concentrated sulphuric acid, by the carbonaceous black-looking residue; whereas with urine similarly treated, but without sugar, there is no residue, and, generally speaking, little or no colour. Colour, when it arises, seems to be derived from the urea, when this principle abounds, otherwise there is no discoloration of the acid. I need scarcely observe that if essential, even this source of discoloration—the urea—might be easily removed. However, after all, I would suggest that it be only used as a trial test. If a small capsulful evaporated to dryness do not strike a black colour when treated with sulphuric acid, we need not make any further analysis; but if, on the contrary, it produce a carbonaceous black, then sugar may be sought for with the expectation of its presence being proved.

* Dr. Prout considers it a binary compound, consisting of water and carbon, or a hydrate of carbon. Upon this principle the sulphuric acid would merely abstract and directly combine with the water, setting the carbon free.

† In reference to the above, it must be admitted that a single drop of a solution of even five grains of sugar in three or four ounces, although it does not darken so soon, yet, on evaporation, it becomes much more black than a drop of urine similarly treated. But when we come to have one part of sugar in one or two thousand parts of

examination, the study of the morbid anatomy of diseases would prove of but little value to either the pathologist or the therapist. It is sufficiently well established that we may very often determine antecedents from their consequences or effects; so from the existing conditions presented upon anatomical inspection, we are often enabled to comprehend the various transitions from health to fatal disorganization. Did morbid anatomy merely consist in an abstract detail of mortal changes, we should derive so little advantage from it, that the pursuit would be scarcely worth the trouble of the investigation. But morbid anatomy, though of the utmost advantage in most cases, yet it occasionally happens that it throws no light whatever upon the subject of research. This is unfortunately the case in the disease now under our consideration; and such must always prove to be the case in diseases which, in different instances, present almost every variety of morbid condition in almost every organ or variety of tissue. Perhaps I cannot offer a better illustration than the signal failure of all those who have attempted to localize the cause of fever. Some, for instance, attribute it to inflammation of the intestinal mucous lining; others to a similar condition of certain glands in the same situation; while others, again, transfer the morbid action to the head, and more particularly the membranes enveloping the encephalon. However, it unfortunately happens for all these theories, that these morbid conditions are frequently observed without any of the phenomena of fever; and again, fever has been fully established, and even proved fatal, nor could a vestige of the essential morbid condition be discovered. In various instances various appearances present, but none constantly and invariably, and therefore they cannot be looked upon as the essential entities in the development of fever.

In the morbid anatomy of diabetes, we derive as little information from the diseased appearances unfolded by anatomical investigation. Indeed, a variety of fatal changes present themselves, but there is no possibility of connecting them with the disease. We find, too, that the most serious changes often present in organs far distant, and, indeed, distinct in their functions, from the urinary organs. Thus very frequently as diabetes advances, and becomes formidable, phthisical symptoms supervene, and, on dissection, the morbid condition of the lungs attendant upon it is formed, and this even in its utmost virulence. The lungs have been found so frequently the seat of disease, and this of a phthisical character, that, in truth, phthisis has been looked upon as the primary affec-

tion, of which diabetes has been considered as only one of the consequences.

The lungs have been found in all the morbid conditions of phthisis, from simple tubercle to extensive excavations; but it is only towards the termination of diabetes, or after the disease has been for some time established, that phthisical symptoms begin to shew themselves. Very often the mucous lining of the bronchial tubes are the seat of a chronic inflammation, with a profuse discharge of pus, the effects of which are extremely exhausting. In one instance of this sort I found the mucous lining soft and pulpy, and in some parts abraded, so that the expectoration presented a sanious appearance; and from its appearance one would have been inclined to pronounce, a large tubercular cavity. But on dissection no disease of the parenchyma was to be seen; but the trachea was ulcerated, and the bronchial membrane presented the appearance above noted. In some cases the lungs have been found congested, and in some even hepatized. Perhaps of all the viscera the lungs more frequently than any other present morbid appearances, and these present great varieties, but the above seem to be the principal ones.

The chylipoietic viscera, with which we may associate the liver, seem often to be the seat of disease; and these diseases assume almost every variety of character, to particularise all which would be wholly inconsistent with our present purpose. The mesenteric glands are frequently enlarged and tuberculated; this was the case in a most remarkable degree in a case which I had an opportunity of examining some time since. These glands were most enormously enlarged, hard, and tuberculated. I did not see the case while alive, but had frequent opportunities of examining the urine, which contained a large proportion of sugar, and the specific gravity usually averaged between 1040 and 1018.

Of course you will naturally expect to hear something satisfactory in relation to the morbid conditions of the kidneys, and from which something decisive might be inferred relative to the disease; but there is nothing satisfactory which I have to communicate upon this point. In some cases the kidneys have been found very seriously affected; in others, they present scarcely any deviation from the healthy condition. In the case to which I have above referred, the kidneys did not present any morbid appearance whatever. However, in general the kidneys present some—however slight the manifestations—appearances of disease. In some cases the kidneys are much enlarged: in one instance I saw them

five or six times their natural size. In some they are indurated, and even tuberculated; in others, even though they should be hypertrophied, they are softened, flabby, and have nothing of their natural firmness. It happens occasionally that the pelvis is much enlarged, presenting the appearance of a large sac or pouch; and this probably occurs only in cases in which large quantities of urine are voided, and to accommodate the retention of which the pelvis gradually becomes enlarged. The kidneys are sometimes found in a highly congested state, but I do not know that they have ever presented the real characters of genuine inflammation, although the consequences, induration, pus, &c. are not uncommon. Lastly, the spinal cord has also been found variously affected; and, indeed, every tissue of the body has, upon occasion, presented morbid appearances more or less varied. Such is a hasty review of the principal morbid appearances which have been observed on the dissection of those who have died of diabetes.

Pathology.—Under this head we shall have many matters to investigate, of which, I fear, we shall be able to offer no very clear or satisfactory elucidation. We have already shewn that diabetes—that is, a saccharine condition of the urine—may exist with or without diuresis; and this appears to be a very important point to establish. Dr. Prout, in his work on the Urinary Organs, hints at not only the possibility, but even the probability of such cases. In the Gulstonian Lectures, too, he states—“A saccharine condition of the urine, in a minor degree, is by no means an unusual occurrence in various forms of dyspepsia, more especially in old gouty subjects; and in this state it can hardly be considered as dangerous, at least not more so than many other urinary derangements.” No doubt they who have been in the habit of minutely attending to the qualities of the urine, will occasionally meet with instances of the description above alluded to; but the two cases I have just noticed seem to be of a very different character. In the first the urine is only occasionally saccharine; but in those which I have brought before you, the morbid condition was permanent, the urine constantly of high specific gravity, and, when the presence of sugar, or some absolutely saccharine principle, was not sensibly manifest, its alternating principle urea was almost invariably found in excess. Here, too, there was no actual diuresis, the urine not being more copious than in the ordinary state of good health; and although thirst was an almost invariable source of distress and

inconvenience, yet the appetite was not preternaturally voracious. Fever and a dry state of skin, it is true, prevailed; but then these phenomena prevail in almost all cases of gastric irritation.

In the great bulk, however, of instances which authors have correctly designated diabetes, there has been distinct and decided diuresis, the quantity of urine greatly exceeding the standard of health, while, at the same time, emaciation and voracious appetite were predominant, if not even characteristic features; but they were wanting in the cases before us. Now to what can these differences in the phenomena be attributed? In both the saccharine condition of the urine, and even to the same extent, are characters which would infer a similarity of symptoms; yet we find in the one variety the patient but barely perceives that his health is out of order, nor has he the slightest suspicion of the nature of the derangement; in the other, he is not only fully sensible of the formidable character of his disease, but experiences the greatest misery and distress, and looks upon life as a source of perpetuation, which he wishes speedily terminated. All these differences are attributable to, and perfectly explicable by, the excessive diuresis which prevails in the severer forms. In order to comprehend how an excessive diuresis can prove so severe a drain upon the constitution, it will be necessary to refer to the following table, constructed evidently with no little labour, by Dr. Henry. In the construction of this table, he obtained the requisite data by evaporating the urine in a steam bath till it ceased to lose weight, and the residual extract became solid on cooling. The table shews the solid extract furnished by a wine-pint of urine, of the intermediate specific gravities from 1020 to 1050, evaporated as above*.

From this table we can readily calculate the enormous draughts made upon the system by this disease; yet it is surprising how little, comparatively speaking, some are reduced under such draughts. I remember the case of a man, at Boreham, named Chapman, and who suffered, and, indeed, ultimately died of this complaint, who passed in the twenty-four hours twenty-four pints of saccharine urine, of a specific gravity of 1043. On looking to Dr. Henry's table, you will find that a pint of urine, of specific gravity 1043, contains 821 grains, or one ounce, five drachms, two scruples, and three grains, of solid matter; therefore the daily draught upon this patient was—

$$\overline{1 \ 5 \ 2 \ 3} \times 24 = 41 \ 2 \ 2 \ 12$$

or three pounds, five ounces, two drachms, two scruples, and twelve grains, of solid extract; yet this man did not emaciate in a remarkable degree till within a short period of his death. In contrast to the above I may mention the case of a woman, named Pratt, who, when I first saw her, was passing daily only ten pints of saccharine urine, of the average specific gravity 1037, which, by the table, gives 708.8 grains, or one ounce, three drachms, two scruples, and eight grains, of solid extract in each pint; consequently—

$$\overline{1 \ 3 \ 2 \ 8} \times 10 = 14 \ 6$$

or very nearly one pound; yet this woman was emaciated to a most extraordinary extent; she also very soon became dropsical, and had symptoms of phthisis in the severest form. Now here are peculiarities that seem at first sight almost inexplicable; but when we consider that Pratt was

affected with phthisis, we may presume that she suffered from other morbid constitutional tendencies in addition to the diabetic; and disease once developed, soon destroyed the patient overwhelmed by so many evils thus called into action. But Chapman did not seem to suffer from any other constitutional tendency, and consequently had diabetes alone to contend with; and had it not been for the most extraordinary and incessant draughts daily made upon the system, this patient might have survived, perhaps, for he was not above 40 years of age when he died. Therefore, when we consider the quantity of solid matter daily evacuated from the system, we can easily reconcile the emaciation and voracious appetite in diabetes.

CLINICAL LECTURES,

Delivered in Jervis-Street Hospital, Dublin,

BY DR. CORRIGAN.

Session of 1838-9.

LECTURE II.

Phthisis. — Division of the Disease into two Stages. — Treatment of the Case by the Iodine Diffuser. — Consideration of the First Stage of Phthisis. — Its Treatment by Bloodletting, Mercury, &c. — Principles of this Treatment.

GENTLEMEN, — The following case brings with it considerations of great importance, both as to the nature and treatment of such affections: —

“John Carroll, a labourer, æt. 28, was admitted on the 15th October, with hæmoptysis. He had been of very intemperate habits, and was continually exposed to repeated wettings. About seven weeks before admission his illness commenced with severe pains in his back and shoulders, accompanied with cough and trifling expectoration, and he wasted in flesh. About a fortnight before his admission, the hæmoptysis set in, and it has continued at intervals up to the present time. His pulse is 72; tongue foul. In the subclavicular region of left side, there is dulness on percussion, with muco-crepitating rattle; natural respiration very feeble, and with very loud bronchophony.

On the 23d October the report was, that the hæmoptysis had ceased, and that the sound on percussion under left clavicle was becoming clearer, and the muco-crepitating rattle more limited, but still audible to the extent of an inch and a half under the clavicle. Pulse 96, small.

On the 5th November an issue was inserted under the left clavicle.

On the 10th the report is, that the cough was less severe; the pulse was only 76; there were no sweats; the sound on percussion under left clavicle was clear, but the muco-crepitating rattle was more audible under the left clavicle, and the expectoration was purulent and abundant.

On the 20th the cough had returned, with pain about the left scapula, and the pulse rose to 88, and became fuller. The crepitating rattle could be heard posteriorly, as low as the inferior angle of the scapula, and anteriorly as low as the fourth rib. He was blistered; the pain and feverishness ceased, and he was then ordered the use of the iodine diffuser three hours per day.

Of the nature of the affection under which Carroll is labouring there cannot be a doubt. It is tubercular disease of the upper portion of the left lung. The

only two diseases with which it might be confounded, are pneumonia and catarrh. The case was at no time sufficiently acute for pneumonia, while the history of the case, the cough and wasting before admission, the hæmoptysis, the dulness on percussion, and the consequent muco-crepitating rattle under the left clavicle, all distinctly point out tubercular deposition in this region as the cause of the symptoms. It might be suggested that catarrh could cause the mucous rattle under the left clavicle, but the mucous rattle of catarrh is always more diffused; and when, as in this case, the rattle is confined to the superior portion of the chest, while, as we examine lower down, the respiration becomes pure, the probabilities are very great indeed against the diseased action being any thing else than phthisis. Were the mucous rattle general over the chest, the diagnosis might be more difficult; but where, as in this case, the respiration is every where pure except in the upper portion of the left lung, and that the muco-crepitating rattle is there constant, there is very positive proof of the mucous rattle having its cause in a diseased state of the tissue of the lung in that situation; and the history of the case, the cough, the wasting, followed by hæmoptysis, refer us clearly to tubercles in the upper portion of the left lung as the disease. There is another sign, if any were wanting, of the nature of the disease, in the attacks of intercurrent pneumonia which have now and then set in. At uncertain intervals, Carroll has complained of pain or uneasiness in the upper part of the left side; and on those occasions the pulse has risen, the skin has become slightly hot, the expectoration has grown viscid, and, on physical examination, the crepitating rattle has been found to extend as low as the angle of the scapula. The proper means having been employed, these symptoms have disappeared, and the crepitating rattle has returned within its old limits. These intercurrent attacks of pneumonia are among the worst and most insidious aggravations of phthisis.

The treatment of a case such as Carroll's may be advantageously considered in relation to two stages — the stage in which he has been since his admission into hospital, and the stage which he himself so accurately describes, which was of five or six weeks' duration, characterized by wasting and cough, with little or no expectoration. I shall first consider the treatment of his present stage, in which there are softened tubercles in the top of his left lung, with intercurrent attacks of pneumonia. I need not tell you how generally hopeless cases of phthisis are, but that recoveries

have taken place where there has been tubercular deposition in a lung, we cannot entertain a doubt. The present is a case in which we may be justified in hoping, at least, for such a result. Cases of phthisis may be divided into two classes; the first, that class of cases in which there is a general serofulous deposition, and in which the deposition of tubercles takes place through a large extent of lung, and principally from the influence of the general serofulous diathesis. This form may be called constitutional phthisis. I believe it is always fatal. The second form is where some exciting cause has produced local serofulous action, and where the tubercular deposition may be confined to the particular site, just as we occasionally see serofulous action occasionally confined to a joint or a gland, without more general deposition. This second form may be called local phthisis. Of this latter form, I hope, is Carroll's case. He was in perfectly good and rude health until seven weeks before admission, when the first stage of the disease set in; and the diseased action has been confined, in a great degree, to its original limits. If neglected, such a case would inevitably degenerate into progressive and general tubercular destruction of both lungs. There is, however, a hope, although a faint one, that the diseased action may be arrested.

This will only be attained by the healing of the serofulous ulceration in the top of the left lung; and it is with the hope of effecting this, that I have put into operation with him the iodine diffuser.

It has often occurred to me, as I have witnessed the surprisingly rapid effects of the local application of iodine externally, both in producing absorption of indolent serofulous swellings, and in healing up serofulous ulcerations, that if a plan could be devised of applying it fairly to similar diseased structures and actions in the tissue of the lungs, we might add materially to our power of combating so dreadful a scourge as consumption. The ordinary inhalers I have always seen patients become tired of. The labour, and trouble, and manœuvring, necessary in using the ordinary glass inhaler will not be borne by a weakened and irritable consumptive patient; while the uncertainty of the dose of the vapour, and the short time it can be used, render it a worthless instrument. Other modes have been devised of administering remedies through the medium of inhalation; but, after repeated trials, I have found the instrument which I now shew you so superior to all the others, and so easy of application, that I have no hesitation in recommending it.

[For a description of the apparatus, extracted from the No. of the Dublin Medi-

cal Journal of March, we refer the reader to the preceding number of the Gazette, p. 49.]

This diffuser possesses many advantages to recommend it. It requires no exertion whatever from the patient, and the extent to which the impregnation of the air which he is breathing with the vapour of iodine, can be regulated to any degree. So strongly can the air be impregnated with the iodine, that I have seen the window curtains of a large bedroom, at a distance from the bed, stained deep blue by the action of the iodine on the starch in the curtains. The air thus impregnated with iodine is not inhaled for a few minutes only, as in the ordinary inhalers, but is breathed for hours without any attention or labour on the part of the patient. The iodine is also diffused through the air mixed with a quantity of aqueous vapour, which deprives it of its irritating properties, and enables the patient to respire it in larger proportion. In using it, I generally direct that the diffuser shall be hung from the roof of the bed. Set to work when the patient retires to rest, it may be allowed to continue in action for three or four hours. The patient falls asleep, and still continues to inhale the vapour. It may be again set in action early in the morning, and continued for three or four hours; while its use does not interfere with reading, writing, or any other occupation in which the invalid may be employed. When the diffuser is used by being suspended from the roof of the bed, when the vapour is partly confined by the bed curtains, the tincture dropping at the rate of about five drops per minute will generally impregnate the air as strongly as the patient can bear it; but if placed on a table in the open room, in which way the patient also sometimes uses it, the tincture may be allowed to drop at a more rapid rate.

The local application of iodine in its most finely divided state—that of vapour—to the diseased surfaces in the lungs may thus be continued for days or weeks, without the slightest distress or inconvenience to the patient, and the quantity thus applied must be considerable. If we calculate that, at the rate of five drops per minute, there are evaporated in an hour five drachms of the tincture, there is then for every hour more than a scruple of pure iodine diffused through the air which the patient is breathing, and a considerable proportion of which must thus come locally into action on the diseased surfaces of the lungs. When we remember the very small proportions of iodine necessary to produce healing of serofulous ulcers externally, often not more than five grains of iodine to an ounce of ointment, we can

easily imagine that, applied through the diffuser, a sufficient portion may enter the bronchial tubes to exercise a beneficial action on the lungs. The iodine administered in this way is sometimes absorbed. Mr. O'Keeffe has tested Carroll's urine, and has on one occasion detected iodine in it. The effects of the use of the diffuser so far in Carroll's case have been very beneficial. His cough has been greatly lessened; his expectoration diminished; and he observed himself, without being asked about it, that his appetite has been increased since he began its use. We shall give the plan a fair trial, and if iodine or any other remedy acting locally on tubercular action going forward in the lungs will arrest that action, this diffuser furnishes us with the means of giving the remedy a fair opportunity.

In the progress of a case of phthisis, such as Carroll's, the attacks of intercurrent pneumonia require to be closely watched. These consist of sudden attacks of congestion setting in on the diseased lung, and they always increase the development of tubercles, or soften down into abscesses those already deposited. Their attack is easily recognized by the heat of skin, the rising of the pulse, and the changed expectoration, which accompany or precede them. With these symptoms the stethoscope discovers an increased extent of crepitating rattle. The change in the character of the expectoration is of itself sufficient to point out the danger. The ordinary expectoration from the tubercular abscess is creamy, purulent, friable, opaque, and without bubbles of air through it; the expectoration on the onset of the attack of congestion and pneumonia presents, in addition, sputa, which are tinged with blood; or if not, are transparent, like white of egg, are viscid, and hold entangled in them bubbles of air of all size. When these symptoms shew themselves, tonics and full diet should be discontinued, a milk or low diet substituted, and leeches applied, and repeated until expectoration has resumed its former appearance.

I have now to recal your attention to what I have called the first stage of Carroll's illness—namely, that period when he complained alone of cough, with little or no expectoration, and during which he sought for no advice or relief. This period, with him, lasted five weeks; and I direct your attention particularly to it, because such a neglected stage is, in very many instances, the stage which is the foundation of phthisis; and the subsequent onset of phthisis may, I believe, in many, very many instances, be prevented

by the timely use, in this stage, of blood-letting, general or local, with the employment of mercury—a remedy which may, perhaps, at first view excite a little surprise, when named as a preservative against phthisis. I shall now give you the grounds on which I base this opinion. The history of the first five weeks of Carroll's illness, is the history of a great number of treacherous cases of phthisis. A patient has been attacked with slight bronchitis, or influenza. Four or sometimes ten weeks are passing over; the cough is continuing, and, as in Carroll's case, with little or perhaps no expectoration; the patient is wasting, there is debility, the appetite has failed, and, to restore it and the strength, the patient is probably using tonics or taking wine, but without any good result. The examination of the chest with the stethoscope gives no satisfactory result. It sounds well on percussion, the respiration is natural, or if there be any morbid sound, it is perhaps only a very slight sibilous sound heard, and only occasionally, under one of the clavicles. On examining such a patient more closely, there is heat of skin, and a pulse always somewhat above the natural standard, with evening exacerbations, through trifling in degree, of fever. Thus the only positive signs are the low fever, the consequent wasting, the quickened pulse, and the sonorous or bronchial cough. But these are enough; while the stethoscopic examination tells us there is neither ordinary catarrh, nor disease of the tissue of the lungs, to give rise to the above symptoms. Pathology and experience of the termination of such cases tell us what has been going on during this treacherous period.

The bronchial tubes of the upper lobes of the lungs are more liable to suffer from irritation and low congestion than the bronchial tubes in any other part of the chest. It is not necessary for us to discuss whether tubercles are or are not a consequence of inflammation; it is sufficient for us to know that the long continuance of a low degree of congestion is most favourable to the deposition of tubercles. Andral says—"On doit admettre qu'ils (ces tubercles) sont produits d'une manière le plus souvent évidente, et quelquefois latente, par un travail qui diffère de l'inflammation proprement dite, non par sa nature, mais par son degré," &c. The upper lobes of the lungs, in their bronchial tubes, are peculiarly liable to this very low irritation, which is so favourable to the production of tubercles.

In such a case as I have just described, omit the tonics and the wine; instead of full diet or nourishing food, given under the fallacious idea of restoring health, put your patient on milk diet, apply leeches to the upper part of the chest, and give a mild mercurial preparation, such as five grains of Hyd. c. Magnesia, every night until the slightest possible effect is produced upon the gums, and the most rapid amendment will follow. There is no need, in such cases, of giving mercury beyond the degree I have mentioned; and remember that in speaking of it as a remedy against phthisis, its use is in removing that degree of low local inflammation which, allowed to remain unchecked, or improperly treated, would terminate in tubercular deposition, and consequent phthisis.

I shall conclude with a case exemplifying the symptoms I have described. In the last week of October a patient consulted me, who for more than two months had been harassed with a ringing cough, without any expectoration. Her breathing was short, and she was occasionally hoarse. She had wasted a good deal, and her appetite was very bad: her pulse was 92. The chest sounded well on percussion, and the respiration was natural. She had been for some time in the country, without deriving any benefit from it. The long continuance of the cough, the wasting, the debility, and the loss of appetite, naturally excited a dread that phthisis was setting in. As she complained of a feeling of oppression over the chest, I bled her to a small amount from the arm, and applied leeches to the trachea. This was followed by the exhibition of Hyd. c. Magnesia, gr. iij. c. Pulv. Ipecac. gr. i. ter in die; and she was directed to discontinue animal food. In a few days the gums were slightly touched, the cough at once ceased, the pulse fell to 80, and her appetite and strength rapidly returned. This case, I think, in conjunction with Carroll's, sufficiently establishes the position that a low degree of bronchial inflammation may subsist for a considerable time; that it cannot be detected by the stethoscope alone; that it is cured by local blood-letting and mild mercurials; that if allowed to proceed unchecked, it would most certainly terminate in phthisis; and that mercury, by removing that low degree of bronchial inflammation, may be employed as a most useful preventive of phthisis.

PHYSIOLOGICAL PROBLEM.

By WILLIAM GRIFFIN, M.D. Limerick.

Does suffering necessarily imply consciousness? Are sentient beings necessarily percipient?

NO. I.

It is a fact familiar to almost every medical practitioner, that a person in an apoplectic fit, if pinched severely in the hand or foot, will sometimes retract the injured limb, and perhaps utter a low groan or expression of suffering. We have the strongest grounds for believing that there is a total unconsciousness in this state, not only in the obvious insensibility of the special senses and the utter impossibility of arousing them, but in the invariable want of all recollection on the part of the sufferer, after recovery, of having experienced any pain or sensation whatsoever. It often occurred to me that it was difficult, if not impossible, to reconcile facts of this nature with the received physiological or metaphysical doctrines on the subject of sensation and consciousness; and to this conclusion I was eventually disposed still more to accede, some years since, on reading accounts of the experiments of Le Gallois, Fleurens, Magendie, and others, on living animals. It had been long universally believed that sensation, consciousness, and volition, were mental acts or functions connected with the cerebral lobes or true brain; but these physiologists have shewn, that although mental consciousness, and of course memory and the association of thoughts, are lost on the removal of those lobes, and, as a consequence, the capability of originating motion, an animal so mutilated may yet live long, is capable of sensation and of the instinctive actions most directly linked with sensations, shews a power of effecting regular and combined movements on external stimulation, and if pushed forwards will continue to advance, even after the impelling power has been wholly expended. It swallows what has been put into the mouth, moves its legs when irritated, and its wings when thrown into the air; but when not excited by any impression made on the senses, appears in a state of stupor; gives no signs of recollection, even of sensations just felt, nor of such emotions as sensations were wont

the ani cannot seek its food, nor
rem obstacles thrown in its way.

It has been further proved that consciousness in its fullest sense, perception, memory, and the association of thoughts—the faculties lost in these experiments—belong strictly to the cerebral lobes; since, if these are left untouched, and the cerebellum removed, they remained unimpaired. An animal deprived of its cerebellum, loses all power of regular and combined movements. If placed on the back, it tries in vain to turn round; it perceives and is apprehensive of blows with which it is menaced, hears sounds, seems aware of danger, and makes attempts to escape, though ineffectually; in short, while it retains uninjured sensation and volition, it loses all power of rendering its muscles obedient to the will.

It appears very extraordinary, in reflecting on these experiments, that after the removal of the brain or cerebellum, or both, sensation and apparent volition should remain; for if it be true that consciousness, perception, and memory, are confined solely to the cerebral lobes, and of course extinguished in their removal, we have either the option of supposing that the motions we attribute to sensation and volition are altogether erroneously so attributed, or that there are in the system two independent centres of consciousness (a supposition which I believe all metaphysicians would look upon as an absurdity); or, finally, that the motions indicate neither sensation nor volition, but are entirely automatic.

M. Magendie has shewn, that after the brain and cerebellum are removed from the adult hedgehog, leaving the medulla oblongata entire to above the apparent origin of the fifth pair of nerves, the animal cries if a hair of its whisker be plucked, or if vinegar be held to its nose, and strives with its fore-feet to rid itself of the object which incommodes it.

Mr. Grainger had the brain removed in a young puppy, which was then put to a large bitch, not the mother, but which was suckling at the time. The puppy, on touching the mamma, threw up its nose and moved the mouth, trying to get hold of the nipple, which, however, was too large. Mr. Barron, who was performing the experiment for Mr. Grainger, then moistened his finger with sugar and water, and put it into

the mouth; when the puppy sucked, the tongue being wrapped round the finger. The same experiment was performed, with a similar result, on another puppy; but the most remarkable fact in the last case was, that as the puppy lay on its side sucking the finger, it pushed out its feet in the same manner as young pigs exert theirs against the sow's dugs.

Let it should be imagined that the brain was not perfectly removed in these experiments, it is sufficient to mention that motions quite as extraordinary, and apparently as much the result of volition, occur in animals after the head has been entirely removed. A frog left at rest after decapitation, will draw up its legs and assume the sitting posture. A decapitated serpent or salamander, when the surface of its body is touched, will turn its headless trunk in the direction of the irritation; and a fowl similarly mutilated, will run or fly, in a staggering or fluttering manner, across the floor, and, after the first convulsive struggles subside, will, if touched with a sharp instrument or a hot iron, wring the injured leg or wing with all the usual manner of pain.

Some of the most celebrated physiologists who were engaged in such experiments, impressed with an irresistible conviction that such phenomena were the result of sensation, were constrained to acknowledge the possible existence of two centres of sensation and voluntary motion, however inexplicable. Others virtually admitted as much, though in a qualified and obscure way. A third and larger number resisted the evidence of expression of pain or of suffering of the resulting muscular motions, and even of such motions obviously adapted to a purpose. They denied the existence of either sensation or volition, as connected with them, and were satisfied to view such remarkable phenomena as instinctive or automatic, analogous to those movements which are excited in internal organs or vessels by the stimulus of their fluids. More lately they have been considered as altogether the result of impressions on the extremities of the sentient nerves, propagated to the spinal cord and reflected back through the motor nerves. But in no instance has the correctness of the notions usually attached to the terms consciousness, sensation, perception, or volition, been questioned.

In support of the conclusion that the

movements in all these cases are automatic or reflex, it is argued that as the head, after its removal from the body, also retains its excitability or apparent sensibility, evinced by the motions of the ears when pricked or touched with a hot wire, we could not admit of sensation and volition in the trunk without acknowledging it likewise in the former; which would be, in fact, acknowledging the metaphysical absurdity already referred to, of two centres of consciousness co-existing in a single being. It is also said, on the same grounds, that as we have the strongest evidence for believing that consciousness, and therefore volition, are functions wholly confined to the anterior hemisphere of the brain, any phenomena, however remarkable, which survive the destruction or removal of those parts must depend upon some other influences; that they are not more extraordinary than the results of other instincts, which are neither connected with nor accompanied by sensation; and that there is not a single instance of automatic motion in parts supplied by spinal nerves, which may not be accounted for on the demonstrated property of the central axes to transmit impressions from the excitable to the exciting nerves, at any part where they are connected with it, independently of the rest.

It must appear, however, on reflection, that even admitting the facts upon which the foregoing inferences are founded — admitting the absurdity of supposing a second centre of consciousness in a single animal, and admitting that those supposed instinctive or automatic motions are the results of a reflex property in the cord, by which, when impressions are received by excitable nerves, actions are originated by motor ones without reference to the brain, the essential organ of consciousness, the assertion must still be regarded as pure assumption, that sensation is not in any degree concerned in movements so strongly characteristic of pain, so long as no more positive evidence of it is adduced than the mere absence of intellectual or mental consciousness. Magendie, Fleurens, and Rolando, have proved to us, that though memory and perception, and of course consciousness in its fullest sense, are lost in the destruction of the cerebral lobes, all the indications of common sensation and the

power of effecting combined a. movements on external stimulation. main. Is it not, therefore, the natural and obvious inference that common sensation, which has survived the destruction of the cerebral organ, can have no dependence whatsoever on it?—and are we to reject this inference because metaphysicians, before they had sufficient data to reason upon, proposed speculative definitions of it, always confounding it with consciousness, and virtually identifying it with perception?

If we were to reject the evidence of analogy in favour of the existence of sensation, in such experiments as have been detailed, it would be exceedingly difficult to prove that any living being except man suffers. In man we have not only the evidence of close analogy, but of universal testimony to convince us. In the brute creation our inferences, absolute as they may be, are deduced wholly from the resemblances of their cries, or writhings, or other indications of pain, to our own. Yet these are so constantly observed throughout the animal creation, in connexion with such injuries as would occasion them in ourselves, that our conviction respecting their sufferings are in no degree less certain than when the same signs are observable in human beings. It is, indeed, no slight proof of the truth and reasonableness of this ready assent to strong and constant analogies, that the same ready belief is intuitively accorded, and pain inferred from cries and complaints in all living creatures by the infant, long before there exists any possibility of its forming deductions from analogy on such subjects. The same instinctive belief operates powerfully even in animals themselves, who evince the greatest degree of uneasiness when they hear the cries or complaints of their offspring or others of their kind.

There are few who have witnessed experiments even on recently decapitated animals, able to resist the strong impression of the existence of sensibility created by their movements on the application of stimuli. When these movements are said to be instinctive, or automatic, or reflex, and dependent solely upon impressions rather than sensations, it is merely assuming the point at issue, since the existence of instinctive or reflex motions offers no proof that they are independent of sensation, and, in fact, were admitted and believed to be

the unity of it, by the most celebrated physiologists, before the doctrine of unmovements by impression assumed its present systematic form.

It is rendered sufficiently probable by the experiments of Fleurens, Bouillaud, and Magendie, that thought and sensation on the intellectual and sentient functions reside not only in different but in distant parts of the nervous system. It seems to be admitted on all hands as nearly certain, that consciousness, memory, perception, and the association of thoughts, are confined to the cerebral hemispheres, while Professor Alison states, "it is now satisfactorily ascertained that no part of the brain higher than the corpora quadrigemina, nor of the cerebellum, is essentially concerned in sensation." Consciousness, therefore, or at least the faculties which are essential to it, belong to the cerebral lobes; sensation, or all the physical conditions necessary, that sensations (*quæ* impressions) may be felt, and that voluntary efforts may excite muscular contraction, belong to the spinal cord. When, with these admissions, we have the facts before us that the former class of functions, the purely mental, with the organs to which they belong, may be utterly destroyed, and yet the latter or sentient functions remain uninjured, it must be acknowledged that we have strong evidence for doubting the correctness of the present metaphysical notions attached to the terms consciousness and sensation.

Setting aside for a while any considerations on the subject of consciousness, let us inquire strictly into the value of the arguments upon which we conclude that sensation subsists after decapitation, and the degree in which it is possible to account for the phenomena indicative of it on any other hypothesis.

Independent of the instinctive belief already alluded to, which is probably mixed up with all our inferences in favour of the existence of sensation, wherever we perceive the usual indications of pain, we are influenced, partly by the correspondence of the movements which take place on injury after decapitation with those induced by similar injury in the perfect animal—partly by their adaptation to a determinate end—and, above all, by their occurring spontaneously, and, as it would seem, originating in pure volition.

The correspondence of the movements in headless or brainless animals, when injured, with the movements of unimpaired ones, is so remarkable that it would be unnecessary to offer an observation on it, if it had not been much questioned, and, in fact, denied, by some late physiologists. Mr. Grainger mentions a salamander in which the posterior extremities were paralyzed by division of the spinal cord, so that "by proceeding cautiously so that the animal could not see the approach of the hand, an entire leg was cut off with a pair of scissors without the creature moving, or giving any other expression of suffering." But in this case it is as difficult to understand why there was no reflex movement as why there was no pain, even taking the loss of the limb into account, in which of course the most violent results of the injury would have been shewn. Perhaps much importance cannot generally be attached to the absence of sentient or reflex phenomena in those experiments, where there has been much mutilation, as it may be dependent on loss of sensibility or of excitability from exhaustion. Volkmann was so sensible of this, that he deduced his proofs from the cases only in which motion occurred, not from those in which it failed, it being evident that reflex motions could take place only where the organic conditions were fulfilled, whereas these must often fail on account of the great destruction by the knife. The instances would be more to the purpose in which the same stimulus applied before decapitation and after it did not occasion precisely the same results, if any such could be well attested. In a frog, Mr. Grainger states that the application of heat to one of the extremities, either anterior or posterior, excited a simultaneous motion in both, an effect he asserts quite different from that produced in a perfect animal in which *the injured limb only is retracted*. As Mr. Grainger, however, in detailing other similar experiments, says merely "*in most instances*," it was found that only the leg belonging to the foot which was irritated was thrown backwards, and as I have myself seen, in the perfect animal as well as in the decapitated, sometimes the fretted leg and sometimes both retracted when only one was pricked with a sharp instrument, attributable perhaps to the varying intensity of the stimulus, his objection

loses much of its validity. In an experiment performed on a rabbit by Mr. Mayo, it is said, that when the foot was irritated, the movement of the limb was exactly similar to that which the animal would make if in indisputable possession of its sensation. In order to ascertain the correctness of this statement, Mr. Grainger mentions that "he pricked the hind foot in a rabbit, the cord of which was entire, when the animal moved the limb to avoid the irritation; but upon dividing the cord, and pricking the under part of the foot, a most violent motion was excited, and both legs were thrown back. Those gentlemen who were present, he states, were particularly struck with the difference of the movements in this rabbit before and after the division of the spinal cord."

In comparing the results of injuries inflicted on parts which are still in connexion with the brain with those inflicted on parts in which it has been cut off by division of the cord, Mr. Grainger seems to forget that in the one case he has the movements of pain, controlled or modified by volition; in the other, the simple instinctive results of pain without any such complication, and perhaps for that very reason the more energetic. It must not be inferred that arguments tending to prove the existence of sensation in parts separated from the brain go also to establish volition, which would necessarily imply the presence of mental as well as sentient functions, and with this understanding, a *strict* comparison could only be instituted, or *precisely* similar results expected, in dividing an animal which in its perfect state has no brain, and stimulating the separated segments. When animals possessing brain are decapitated, we can expect to witness only the instinctive effects of pain on stimulation, those movements most closely linked with their sensations, and these can bear no nearer comparison with the results of like injuries in perfect animals of the same kind, than as they are both admitted to be characteristic indications of suffering, and such as are known to be instinctive with the animal. Mr. Grainger seems to think the motions resulting from injury are more violent after decapitation than before. I have myself found so in experimenting upon two kittens which were taken out of a pond in a very enfeebled state, where they had been flung for the purpose of

drowning them. Pricking immitations excited only the feeblest the previous to decapitation, but after the slightest touch of a sharp instrument occasioned ready retraction of one or both limbs. Dr. Volkmann states that a stimulus produces reflex motions in decapitated amphibia, which, previous to decapitation, had no such effect. That these differences are partly attributable to the influence or operation of the will, as already suggested, there can I believe be little doubt. There are few persons who have not experienced sudden involuntary starting of the muscles of the limbs or of the whole body, and such motions are always found to take place most readily when the cerebral system is in a state of exhaustion or rest, as after great fatigue, or when dropping off to sleep, just at the time when consciousness and volition are at an end. A gentleman affected with partial paralysis of one side once mentioned to me, that whenever he put out the weak limb in progression it always took too long and too forcible a step—going off, in fact, with a jerk, for want of the due control of the will. Such facts sufficiently prove that the influence of the voluntary powers of the brain is constantly acting, and perhaps more frequently in controlling or modifying instinctive or sentient movements than in supporting or increasing their energy. I do not believe, however, that the absence or presence of the cerebral influence or operation of the will can explain altogether in all instances the differences observable in the effects of stimuli applied to perfect and to decapitated animals. We do not as yet understand all the causes which may effect these movements, nor can we thoroughly explain to what extent or in what manner even the known causes may influence or effect one another. To this conclusion the late experiments of Dr. Volkmann appear also to have led. "The will," he infers, "prevents reflex motions, because, of two opposing forces, the weaker must yield, and the power of the will is often sufficient to keep muscular motions in control. It is not asserted, however, that decapitation favours the production of reflex motions, solely by the removal of the mental influence: on the contrary, it appears probable that there are other, but *unknown* causes engaged; for the in-

the unity the nervous action to cross removement to filament is so great in decapitated amphibia, that it would require a very uncommon degree of mental influence to control them, on the assumption that it was the only controlling power."

But if, after all, there be a doubt that the movements of decapitated animals present as characteristic indications of sensation or suffering as the movements of perfect ones, it is fully compensated for by their obvious adaptation to a determinate end, and their frequent spontaneity, both of which phenomena are wholly inexplicable if the existence of sensation be rejected. Dr. Volkmann states that a decapitated tortoise, when irritated, conceals itself beneath its shell, and a decapitated frog comports itself according to the nature and degree of the irritation. When its fore feet are irritated, it withdraws them; when further irritated, it withdraws them further; and when yet further irritated, it draws them in below the belly, and changes the sitting for the recumbent position. When the posterior extremity is violently irritated whilst it is in the sitting position, it will bound forwards; when roughly seized in the thoracic region, it will plant its fore feet upon the hand which holds it, *and try to free itself*; and when the skin of the abdomen or back is seized with a forceps, it is by no means uncommon for the mutilated animal to *scratch the part with the posterior extremity of the corresponding side*. Mr. Grainger states that, "upon irritating the cloaca in a green frog which had been decapitated, the most violent motions were excited in the hind legs, and repeated attempts were made by the limbs to remove the instrument with which the cloaca was touched." This fact (he says) he has since repeatedly seen in the green and common frog, both when the head was removed, and when the spinal cord was divided in the back; and he has also noticed it in the common fly and other insects after decapitations. He has observed, too, that if, after having cut off the head in frogs, fire is applied to the fore part of the trunk, *violent motions to remove the source of excitement are made*." It is, however, needless to multiply facts of this nature; they are now familiar to every vivisector, and prove most fully that the motions which result from irritation in decapitated animals possess all

the characters of adaptation to a determinate end.

Dr. Marshall Hall, however, denying the sentient nature of the spinal cord, will not admit that either ordinary indications of pain, or the adaptation of movements to a determinate end, are any undoubted evidence of its existence. Spontaneity of action alone, he admits as the true test of sensibility; and this, with consciousness, he believes disappears after the removal of the brain, chiefly because decapitated animals, when once they become quiet, remain immovable in their assumed position, if not irritated, as long as life remains. This latter (if the fact) would tend to prove absence of thought and volition rather than sensibility; but the experiments of numerous physiologists are directly opposed to it. Decapitated frogs, after remaining at perfect rest for some moments, are known to assume the sitting posture. In the experiments of Fleurens and Magendie, in which the brain was removed, the animals, when pushed forward, continued to move after the impelling force must have been wholly expended. Mr. Grainger found, on pricking the feet of the posterior half of the body of a salamander, which had been cut into two pieces, that the motions of the limbs and tail which followed were several times repeated, from the one application of the stimulus; and Dr. Marshall Hall states that a *Coluber natrix*, whose spinal marrow was divided between the second and third vertebræ, continued moving for a long time when once irritated, the movements at last gradually subsiding. Both Mr. Grainger and Dr. Hall explain these apparently spontaneous actions not as the result of sensations but of impressions, their continuance or repetition arising from new parts of the limbs or surface of the animals coming in contact with the table or ground at every altering position, and so occasioning new reflex movements. On this supposition, however, it would be more difficult to understand why the motions should cease at all, than why they commenced, at least as long as any power to move, or excitability remained. It would also be difficult to explain their ceasing gradually, as one might anticipate they would do if dependent on sensation, instead of suddenly, as a movement originating in mere impression might be expected to

the unimpaired existence of, after the removal of the brain, it is difficult to say, unless the scepticism on the subject depends, as I believe it does, on erroneous notions of both consciousness and sensation derived from abstract reasonings on the mental faculties. Before we can advance one step further in this inquiry, it is essential to shew that these erroneous notions do actually exist, and have been universally received by psychologists from the remotest period to the present hour.

It is perhaps true, that we can arrive at a knowledge of the human mind only by reflection on its acts and operations; but it can be admitted solely on the understanding, that the inferences from these reflections are strictly tested by a comparison with the inferences from physiological investigations; and I question much whether, in any case, the metaphysician would not reason more securely if he first investigated accurately the construction and properties of the several nervous masses or organs with which the faculties of the mind are known to hold connexion, and so laid the foundations of his future and more abstract inquiries in anatomical and physiological facts, which no new views or discoveries could alter.

The very vague manner in which the terms mind, consciousness, perception, volition, and sensation, are employed by almost all writers, would sufficiently convince one of the truth of this, if it were not otherwise obvious. The term mind is sometimes used to express the understanding, thoughts, or intellectual functions only; sometimes these and the sentient, and sometimes the sentient alone, as when pure feeling or sensation is spoken of. Consciousness is used almost indifferently for perception or sensation, and these latter often as indifferently for one another. The term volition is applied with equal uncertainty, half the disputes relating to the voluntary or involuntary character of muscular action having arisen from a mere disagreement as to what volition means. Let us consider what we are to understand by these several terms, and first—of consciousness and volition.

[To be continued.]

OBJECTIONS TO MEDICAL CORONERS.

To the Editor of the Medical Gazette.

SIR,

MAY I be allowed a few words in explanation of a former communication you favoured me by inserting in the *GAZETTE*, the purport of which Dr. Fife does not seem exactly to have comprehended:—

I never intended to convey the idea that medical men were less able to discharge the functions of coroner than the present holders of that office; indeed, judging from the description of persons sometimes appointed to it, in the provincial districts, I can readily allow that they are more so. But it will be recollected, that a medical coroner has been held out, as the great panacea for all the evils and abuses of coroners' inquests, which have recently been so frequently brought to light. My fear is, that those whose duty it is to occupy themselves in remedying evils, which have been so abundantly proved, will now rest content, satisfied that the specific has been applied, and that the cure will result. Observe, you invest the *medical coroner* with a function which cannot appertain to the non-medical coroner, namely, that of criticizing the validity of the medical testimony, and that without any security whatever of his ability to do so. I do think that medical men will be acting foolishly by aiding in thus placing members of their body in a situation to dispute, or even condemn their statement or opinions, without any means of judging of or ensuring their capabilities for this delicate and difficult task, not electing them themselves, but receiving these their judges at the hands of men entirely unqualified to decide upon their merits. If the simple election of a medical man were to ensure an efficient medical coroner, the duty of the electors would be simple, and many of these remarks inapplicable.

I hope I have no disposition to speak disparagingly of the acquirements of my brethren, and no one can rejoice more than I do at the rapid progress of professional improvement; but no candid man will deny, not only the hazard, but the great difficulty, of finding medical men having a sufficiently practical

acquaintance with medical jurisprudence, to enable them to comment before an ignorant jury upon the opinions of the medical witnesses. Suppose the medical coroner and medical witness to be at issue as to the value of a piece of testimony. Who is to decide in a case so likely to happen? Verily, the decision of a question in medical jurisprudence will then rest with the jury!—a body of men, in all probability, wholly guiltless of any knowledge in the remotest degree bearing upon the subject. Certainly, this ridiculous state of things, by shewing still further the absurd nature of this tribunal may hasten its abolition; ill-adapted as it is for working out its professed objects at the present day, however useful it might have been at its first establishment.

But supposing that coroners' juries (however absurd in their constitution, and however inferior to the mode adopted on the continent for conducting such inquiries) are likely to continue, I ventured to suggest the appointment of district medical officers, who should become official witnesses before the coroners' courts in all cases of unusual death. Dr. Fife mistakes the object I have in view, when he observes, that to examine these witnesses, the coroner must be well informed on subjects of medical jurisprudence. The suggestion arose from the anticipation of the possible incompetency of the coroner. I consider that these officers, from the severity of their examination prior to their appointments, and their subsequent experience from constant opportunities, would become *authorities*, whose opinions should guide the coroner and jury, as far as the points submitted to their examination were concerned. Thus, say a man dies, who is supposed to be poisoned. The medical officer, after a careful *post-mortem* analysis of contents of stomach, &c. &c., arrives at his conclusion whether the deceased has died from poison or not. As far as this point is concerned, his decision should be final, and the jury should proceed to act upon it as a fact, confining their attention, in the case of poisoning, to discover whether it resulted from accident, suicide, or murder. Dr. Fife objects, that an officer of this description would displace the ordinary medical man, who, as matters stand at present, is now called in. This is not exactly the case; but even if it were—if the

true interests of the public required such sacrifices, medical men must be prepared to make them; at the same time relieving themselves of a responsibility that many would be glad to be rid of. But the fact is, that the ordinary medical man would be called to accidents, &c. &c. as at present, and his remunerations would be the same; but he would be obliged to call in the aid of the official, in case of death, to conduct all subsequent examinations and processes, which, if they involved any delicate or unusual investigations, he would himself, in nine cases out of ten, be unable to do justice to.

I agree with Dr. Fife, that the duty of the coroner should be to assist the jury (ordinarily lacking assistance of some kind woefully) to the utmost of his power; but I would wish to guard against his attempting to assist them beyond his power, by substituting his opinion for that of the medical witness, who may, in some cases, be better informed than himself, notwithstanding which, both the jury and the public at large would certainly be biassed in favour of that of the coroner.

I am, sir,

Your obedient servant,

JOHN CHATTO.

London, April 3d, 1839.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abréger.”—D'ALEMBERT.

A Short Treatise on Typhus Fever.
By G. L. ROUPELL, M.D. Physician
to St. Bartholomew's Hospital, &c.

It was scarcely to be expected that the fever which raged with such fearful virulence during the last year, among the poorer classes of the metropolis, and which still exists, though with a somewhat decreased intensity, should pass by without some notice from those under whose care a large proportion of the sufferers fell. We are glad that a subject of so great importance has fallen into the hands of the present author, whose offices at the Dreadnought Hospital Ship and at St. Bartholomew's have afforded the most favourable opportunities for observing every feature and phase of the disease. We shall give the best idea of how well he

has fulfilled his undertaking, by a brief abstract of the work before us.

The first object which it professes, is to prove that the typhus fever now prevalent, as well as that which raged particularly in 1831, and those described by Hildenbrand, Huxham, Pringle, Armstrong, Rasori, Louis, Chomel, &c. under various names of adynamic, gaol and hospital fever, nervous fever, &c. constitute a species of exanthema which is in all its essentials analogous to the eruptive fevers hitherto included under that title. This idea was, it may be remembered, expressed by our author in a paper read in 1831 at the College of Physicians: he then thought it original; but now, with a candour unfortunately too rare in the present day, he yields the honour of originality to Professor Hildenbrand, of Vienna—an author so little known in this country, that “not a single copy of his work in the original could be met with in any of our libraries.” The grounds for considering typhus fever as an exanthema are as follows:—It is accompanied by a distinct rash; this is obscurely, yet certainly mentioned, by Huxham, Pringle, Rasori, Bateman, Sauvages, and Armstrong, and more distinctly by Chomel, and Louis, and Hildenbrand. Dr. Roupell has found it so constantly, that, allowing for circumstances which sometimes render it peculiarly difficult of detection (as its partial and fugitive appearance, its being unaccompanied by sensation, &c.), it may be considered as regular a symptom as the eruption of small-pox or measles. This rash most frequently appears on the fourth or fifth day of the disease; but, like those of measles and scarlatina, may be accelerated or retarded, or altogether absent; and, like them, is irregular in the time of its disappearance. “In truth, there is no peculiarity or anomaly (of the eruption) in typhus, which may not be found exemplified in scarlet fever, measles, or small-pox;” and the evidence which the author adduces, and the quotations he makes, sufficiently prove that the exceptional cases occur with nearly equal frequency in each disease.

Typhus fever, like the other exanthemata, may spread by infection. The obituary of our own profession affords too lamentable a proof of it; at least five of its members died within three months in 1838, and many more were at-

tacked, but survived. At St. Bartholomew's six pupils were attacked during the session of 1837-8, and as many in the preceding; and among the nurses in that establishment, “infection was almost universal.” But the most convincing proof was presented in 1831, when fever was so prevalent in the Refuge for Distressed Seamen, on the north side of the Thames, that it was found necessary to have a separate part of the house allotted to them. Numbers of the patients, however, were sent to the Floating Hospital, in which the fever did not exist previously. “The disorder then imported soon spread itself over the ship; patients admitted for surgical and other complaints were attacked; the residents on board suffered from fever of a similar kind, and the immediate attendants were severely visited. Of seven nurses employed for the fever patients, six were attacked; and from them the fever a third time made its appearance in a fresh situation, viz. in their houses on shore.” All the attendants at the Refuge suffered from it, but there was no such disease on board other vessels near the Hospital Ship, nor yet on the south bank of the river, till it was carried there by the nurses. Dr. Roupell's evidence, therefore, with that of Dr. Tweedie, who shews that, with one exception (Dr. Bateman), all the “medical officers, matrons, porters, domestic servants, and nurses, and even the laundresses, at the Fever Hospital, have invariably been the subjects of fever,” can no longer permit a reasonable doubt of the communication of typhus by infection.

Although “no prospect of complete immunity from a second attack can be held out to those who have once suffered from this fever,” yet there appears to be some immunity, at least for a time; and similar exceptions to the general rule that other eruptive fevers affect the body but once are now so frequent, that in this character the analogy of typhus to them cannot be said to fail. It has, in general, “a certain period of duration,” about twenty-one days; and here, again, the variations to which it is subject are met with in equal frequency, and of the same kind, in other exanthemata.

In severe epidemics of typhus, as in those of scarlatina and measles, cases sometimes occur in which the disease presents itself in a singularly mild and

modified form, lasting but a short time, and devoid of many of its most formidable symptoms, yet clearly identical in their nature with the most marked examples. In typhus, as in small-pox, scarlet fever, and measles, petechiæ are occasionally present, and hæmorrhages, especially epistaxis, are not uncommon concurrents. In all these diseases, again, erysipelas is a frequent concomitant or sequel—in all there is a great tendency to suppuration in various parts of the body, with but little disposition for adhesive inflammation—in all a remarkable liability to gangrene and sloughing, and to the peculiar train of symptoms termed “putrid.”

In all these particulars, then—in both the essential and the occasional characters—typhus is clearly analogous to the eruptive fevers generally. We can only enumerate the facts which the author exhibits in detail, and in all cases supports by brief but perfectly apposite cases; but we have dwelt the longer on this part of the work, because, besides having novelty on its side, it is of the utmost importance not only nosologically, but practically, to prove that our knowledge of scarlet fever, measles, &c. may be applied by analogy in our investigations of so interesting a disease as typhus fever. In our opinion Dr. Roupell has fully proved this point, by fair and lucid arguments; he meets the chief objection, drawn from the improbability of the rash being so long overlooked, by the fact that it is mentioned more or less distinctly by all the writers of eminence, though not regarded by them as essential; and by the similar error in which measles and small-pox were confounded for 800 years, and measles and scarlatina not distinguished till the year 1781, though both had existed from the earliest records of medicine.

Dr. Roupell believes that “the poison of typhus enters the blood, and so infects the system. It does not, however, follow that the disease will manifest itself, even although the circulating fluids are so contaminated or infected as to produce the disease in another. The symptoms, it would seem, arise not from the admixture of the poison with the blood, but from the action of the fluids thus diseased upon the vascular and nervous systems.” In the more severe cases, inflammation of various tissues, especially the cellular (the mu-

cons of Meckel), occur; and the author inclines to the view that in most of them phlebitis, commencing in the smaller or the capillary veins, is the fundamental cause of the severest symptoms of typhus. The arguments for this are, of course, almost entirely analogical, being drawn chiefly from the similarity of what are commonly called typhoid symptoms, supervening after poisoned wounds and other injuries, to the more alarming symptoms of typhus. We cannot enter upon all the evidence in favour of this view; but it is at least as well supported as the encephalitic theory of Dr. Clutterbuck, or the gastro-enteritic of M. Louis.

We pass on to the treatment, in which the author is as practical and judicious as he is sound in his nosological arguments and ingenious in his pathological theory. In reference to bleeding, having shewn the confusion and contradictions of previous writers, Dr. Roupell says, “In some diseases, if you doubt, you should bleed, but in typhus the contrary obtains. That this remedy is very rarely to be employed in a late stage, there can be no doubt, but that it is eminently useful in the earlier ones I am quite convinced. Many earlier severe symptoms may thus be mitigated and controlled—many of the after consequences prevented.” Emetics, also, he recommends in the early periods of the disease: they “may be given with immediate advantage at any time within the three first days; after this their benefit is less obvious, and seems to diminish in proportion as they are delayed.” On purgatives he expresses nearly the same opinion; but says that they may, in small doses, be employed at any period of the disease in which they seem to be required, without the least fear. Of mercury, large quantities should not be given, unless in cases which present urgent inflammatory symptoms, but small doses are generally useful as an alternative. Of salines he speaks with less certain praise; of autumn, “it should only be used where there is inflammatory action and strength,” and therefore, in many cases, notwithstanding Rasori’s commendation, it is absolutely inadmissible. “On ordinary occasions and in general practice, Dr. Currie’s suggestion of cold affusion over the body is unadvisable and unnecessary; but cold drinks are as innocent as they are agreeable to the

patient. Stimulants are absolutely necessary at certain periods, in many cases of typhus. There is no one period at which they may not be necessary, though they are rarely so in the earlier stages, and are more serviceable in the decline of the disorder. To know the proper moment for their administration is the greatest difficulty: the great object must be to maintain strength enough in the heart to enable the circulation to continue."

With some further remarks on minor points of treatment, the work is summed up with reference to the subjects of which we have made abstracts. It will be seen how important they are, and we will only say that they are all treated in the manner which their importance merits.

Hints to Mothers, &c. By THOMAS BULL, M.D., Physician-Accoucheur to the Finsbury Midwifery Institution, Lecturer on Midwifery, &c. Second edition, greatly enlarged. London, 1839. 12mo. pp. 305.

To the question, "What is the use of a new-born child?" we would offer the answer of Benjamin Franklin—"It may become a man;" yet to enable it to do so, requires a degree of watchful care to be bestowed upon it, directed by knowledge and judgment, which few who undertake the task possess. To furnish the knowledge requisite for the successful physical culture of the infant is quite as benevolent an office, and as necessary a one, as to provide the means for its future mental and moral training. Therefore do we regard favourably every work emanating from so competent a source, which tends to make the members of the next generation more healthy than their predecessors. Dr. Bull, in the volume before us, justly considers that the manner in which the pregnant female acts in respect to her own health and habits has a most material influence on the subsequent structure and health of her offspring. To the parent he addresses his first advice, detailed in language so clear, yet so devoid of every approach to indelicacy, that those who read and apply his instructions cannot fail to benefit by them. The order in which the subjects are treated is not only lucid, but such that his book constitutes a volume which may be successively referred to

in each advancing month of pregnancy. The disorders liable to occur after confinement are treated of in a similar manner; and the remaining portion of his pages are devoted to matters concerning nursing, whether by the mother, "wet-nurse," or bringing up "by hand." A few rules and suggestions for the management of the early years of infancy are added; and a copious index guides those who may wish to consult it for any special purpose, or to obtain information quickly how to act in cases of emergency, such as when the child is still-born.

We have one exception to take with it, namely, with some of the formulæ; not that they are inappropriate, but that in either compounding, or copying them out for a chemist, mistakes are apt to be committed which might be fatal. We submit to the consideration of Dr. Bull the following:—

Battley's Sedative Solution of Opium, one drachm; Compound Tincture of Lavender, half an ounce; Distilled Peppermint water, six ounces. Two table spoonsful to be taken before retiring to rest.

What correct criterion are common people to use to know what a drachm is? And an excess of Battley's sedative is not a very safe sleeping draught. Such may be omitted with advantage.

As a subject of physiological curiosity, should any reader doubt, from the solitary case cited out of Franklin's Narrative of a Journey to the Frozen Sea, the possibility of a male to give suck in Humboldt's Personal Narrative may be found such a number of well-authenticated instances as may remove the incredulity of the most sceptical.

This little manual will prove useful exactly in proportion to the extent of its circulation. We therefore wish it a wide diffusion among those for whose benefit it has been written.

A Manual for Students who are preparing for Examination at Apothecaries' Hall, &c. By WILLIAM MEADE, M.R.C.S.

THE object of this book is sufficiently explained by its title, and few words regarding it will suffice. It contains a great deal of judiciously-compiled information, calculated to be useful to the student who is *cramming*. Midwifery

and surgery are, however, not touched on; the physiology and, we may add, the anatomy, are rather meagre, and an index, or a table of contents, is much wanted.

MEDICAL GAZETTE.

"Licet omnibus, licet etiam mihi, dignitatem
Artis Medicæ tueri; potestas modo veniendi in
publicum sit, dicendi periculum non recuso."

CICERO.

TREATMENT OF POISONING.

A WRITER in the *Gazette des Hôpitaux*, who would appear to be strongly imbued with the doctrines of the Italian school, gave a commentary, not long since, on the treatment of poisoning, his text being four cases which occurred in the London Hospital; and though his observations, if judged by received opinions, are somewhat paradoxical, yet they belong to an ingenious thinker, and cannot be studied without profit, even by those who read only to refute them.

The treatment in the original cases was as follows:—

CASE I.—A man who had taken two ounces of sulphuric acid was admitted into the hospital twenty hours afterwards. He was ordered several doses of calcined magnesia (which he swallowed with difficulty), and mucilaginous drinks, while bottles of hot water were applied to his feet and legs; but these remedies were too late; the patient continued to sink, and died in about three hours after his admission.

CASE II.—A seaman was admitted a quarter of an hour after having swallowed 140 drops of prussic acid. The stomach was immediately emptied by the stomach-pump, and a solution of carbonate of ammonia was injected, and then an ounce of brandy, and these injections were repeated. The face and chest of the patient were sprinkled with cold water; he became quiet, having previously been convulsed, and recovered his consciousness. He was then

undressed, and put to bed; bottles of hot water were applied to his feet, and mustard poultices to his legs; a turpentine clyster was administered, which acted copiously. The patient now fell asleep, and remained so for several hours. On awaking, he was perfectly calm, complaining only of slight headache; and in a few days he went out cured.

CASE III.—Rebecca Adams was admitted half an hour after having taken twopennyworth of acetate of lead. About a pint of the compound infusion of roses was injected by the stomach-pump, in order to decompose the poison, and form an insoluble sulphate of lead; and all the fluid in the stomach was then withdrawn. She was put to bed, hot fomentations were applied to the legs and feet, and several doses of camphor and ether were administered. She was much benefited by these measures, and an hour afterwards she took an ounce of castor-oil, which acted briskly.

The following morning the patient had a decided fever, and intense pain at the pit of the stomach. The saline mixture, with leeches and blisters to the præcordial region, relieved her considerably, and she finally recovered.

CASE IV.—A girl of 19 was admitted in the evening, six hours after having swallowed half an ounce of oxalic acid. From the time which had elapsed, the stomach-pump was thought useless, and an ounce and a half of castor-oil was prescribed, after which she slept till the next morning. On waking, she complained of pain in the epigastrium, for which twenty leeches were applied, and a saline and mucilaginous draught administered. She recovered.

The Parisian critic comments upon these cases, and discusses the general question, in the following manner:—

"In every case of poisoning there are two principal indications to be fulfilled; the one is, to remove or neutralize the poison; the other, to combat the dynamic effects of the injurious substance. Much has been done to fulfil the first indication, and, thanks to the progress of chemistry, we know the antidote for almost every poison; but all yet re-

mains to be done with reference to the second indication.

No chemist, we think, will allow that every poison has a known antidote; and few physicians, we hope, will agree with our contemporary that *all* remains to be done, as far as medical treatment of the symptoms is concerned.

Our chemical agents, he adds, intended to neutralize the poison, do not always reach the stomach in time, and the stomach-pump is not in every case at hand; while, as to emetics, besides their not being always swallowed, they sometimes do not act, and sometimes when they do, it is too late. He asserts that the fatal effect of poisons does not in general proceed from the disorganization of the œsophagus and stomach which they cause; they do not destroy life till they have been absorbed into the blood, and have acted upon the vitality of the frame. This is proved—

1st. By injecting the same quantity of a poison into the veins, when its effects are both quicker and more formidable than when introduced into the stomach.

2dly. By a given quantity of a poison in solution introduced into the stomach, or poured upon the surface of a wound, acting far more violently than when in a solid state. In the latter case, though the doses may have been tripled or quadrupled, they do not produce vital effects in proportion to the quantity; this is accounted for by the slowness with which the poison is absorbed when in this form.

3dly. By a poison proving fatal in a few seconds, without leaving a slough in the stomach or elsewhere.

Hence, says the French commentator, when a poison has been taken either into the stomach or the rectum, and it can no longer be evacuated or neutralized, the duty of the physician is, first of all, to combat its vital or dynamic effects, by remedies which act in a con-

trary manner; and, secondly, to treat its local, mechanical, or physico-chemical effects, which commonly consist of irritation, inflammation, or mortification of the tissues with which the poisonous substance has been in contact; but as the local injury does not kill immediately, it is the dynamic impression which must first be resisted.

To fulfil the first indication, it is of course necessary to have a clear idea of the impression produced upon the system by a given poison; otherwise the physician will be apt to go astray, and administer medicines not only useless, but absolutely assisting the action of the poison. A man, for instance, has swallowed sulphuric acid; he is bled, and leeches are applied to the epigastrium; milk, albumen, and gum-water, are given him; and then we have a long dissertation on the arborizations and coagula found in the post-mortem examination! If *la médecine expectante* had never been blameable before, it would be so in a case like this.

Our Parisian brother then proceeds to comment on the London cases.

The first was a case of poisoning by sulphuric acid, and the patient was in a state of general depression, with a pale face, thready pulse, and cold sweats. To these the commentator here adds *apathy*; whereas, in his original account, he mentions *extreme anxiety*, which is quite the reverse. Compare, he says, these symptoms with those which have occurred in the cases of poisoning by the same acid, and you will be obliged to adopt the conclusion of Rasori and Tommasini—that sulphuric acid is a depressing or contrastimulant substance of the first order, and that it kills by lowering and exhausting the vitality of the frame. Hence it follows, according to the French authorities, that the dynamic effects of this poison should be combated by stimulants—such

as ammonia, ether, alcoholic drinks and opiates. It has been shewn by experiments on animals, that when this variety of poisoning is treated antiphlogistically, death is much hastened; while large doses of brandy, ammonia, diluted alcohol, and morphia, relieve the symptoms, and prolong existence, or even effect a cure if the dose of the poison was not too large or the assistance too late. When such a case, therefore, occurs in practice, after having endeavoured to remove or neutralize the poison, the case is to be treated like one of poisoning by the bite of a viper—namely, with ammonia and ether, by the mouth and in a clyster; the body is to be rubbed with hot brandy, and a potion containing morphia is to be administered, as well as enemata of hot wine. This last expedient is particularly advisable, as the experiments of Cramer and Brinckle shew that drunkenness, caused either by wine or brandy, is dissipated by sulphuric acid.

These are the means to be first used to relieve the depression of the system; yet we are not to forget that the local and chemical injury, which is of an opposite kind, must also be attended to, as the re-action which it causes is equally to be feared. The preceding remedies, however, are first to be administered, and it is then only that antiphlogistic treatment can be successfully employed.

Such are the chief arguments of the *Gazette des Hôpitaux* on the proper method of treating this variety of poisoning: we fear that their practical application would not be very easy. In the case of the patient in the London Hospital, not only was there extreme anxiety instead of apathy, as we have already remarked, but a burning sensation extending along the whole œsophagus; so that, we apprehend, neither Rasorion nor Tommasinian would have

ventured to administer ammonia or ether. When treating the primary depression, the physician must anticipate the inflammation of the stomach which will soon ensue; and how is this to be done, if he trusts to the doctrine of the Italian school?

In his observations on the next case, our contemporary goes so far as to say that the nature of the action of hydrocyanic acid is not different from that of the sulphuric; and he adds, that although it has the property of exciting muscular contractions, yet its real effect upon the vital system is that of a contra-stimulant. We believe the truth to be, that hydrocyanic acid, if the dose is small, is not productive of any remarkable depression; whereas, if the dose is very large, the brain is utterly exhausted, and immediate death is the result*. It is the sedative effects of this poison which the physician is called upon to treat, and it is fortunate that there is little or no difference of opinion as to the best antidote. Ammonia and brandy, which the *Gazette* mentions, and the cold affusion, which it omits, are, no doubt, the fittest remedies: there is also good evidence in favour of chlorine.

Sugar of lead, the poison swallowed in the third case, is another contra-stimulant, says our contemporary, and its effects are to be counteracted by the exhibition of opium. He adds, that it is a strange illusion to suppose, as some do, that sulphuric acid may be substituted for opiates. It is hardly necessary to observe, that while the critic is afraid of sulphuric acid, because it is a contra-stimulant, like the poison which it is to combat, those who give it expect that it will combine with the lead

* For instances in which it has appeared to possess a stimulating power the reader may consult the experiments of Dr. Jörg, of Leipsic. *Materialien zu einer künftigen Materia Medica.*—Materials for a future Materia Medica.

still remaining in the stomach or intestines.

The fourth case is dismissed with the utmost brevity: the physiological phenomena resulting from poisoning with oxalic acid are the same as those produced by the preceding substances, and the treatment is consequently to be the same.

But imagine an opposite case; suppose a stimulant poison to have been taken, such as opium, or alcoholic beverages—what is to be done then? In a case of poisoning by opium, which the critic lately reported, the strongest stimulants, such as ammonia and brandy, only made the symptoms more intense. How could it be otherwise, he asks? Look at the man who is dead drunk, either from alcohol, or opium: the pulse is full and strong; the face of an apoplectic cast; the respiration stertorous, with moaning, and the signs of cerebral congestion. In such a case the indications are exactly the same as in sanguineous apoplexy; the first remedy is bleeding, after which come contra-stimulant medicines, such as dilute sulphuric acid, belladonna, &c. These recommendations are rather startling. To bleed before the poison is removed would favour its absorption; the sulphuric acid would form a sulphate of morphia, and thus, perhaps, increase the activity of the opium; and belladonna, in its power of disturbing the brain, has a great resemblance to the poison which it is intended to counteract!

Experience seems to say, that ammonia is beneficial against intoxication; but if so, the Italian school is wrong, and, indeed, most other schools too, for alcohol and ammonia are both stimulants. The Parisian annotator denies the fact, and supposes that there has been a mistake about the matter, "ainsi que le fait observer, bien à propos, le Professeur Giacomini." He

says that he was not successful in a case of intoxication which he treated with ammonia, and shall keep to his present opinion till the contrary is demonstrated. Perhaps, however, without waiting for any new lights, the solution of the difficulty may be, that slight intoxication is relieved by ammonia, while the remedy has no effect, or a bad one, in those graver cases where a deep impression has been made on the cerebral circulation:—

— Eræ: parce, Liber,
Parce, gravi metuende thyrso!

CLINICAL LECTURES ON SURGERY,

Delivered at the Midd'esex Hospital,

By MR. ARNOTT.

1. *Symblepharon, the effect of Mortar.*
2. *Iritis.—Use of Turpentine.*
3. *Chronic Corneitis.—Use of Iodide of Potassium.*
4. *Deafness from Disease of the lining Membrane of the Tympanum.—Use of the Acetate of Lead.*

On looking at the right eye of the boy, Henry Wicks, who was admitted two days ago, the impression produced upon those who are not familiar with cases of this description, is, that it is one of pterygium, there being a fleshy membrane covering a portion of the sclerotic coat and cornea, and formed apparently of thickened conjunctiva, redder and more vascular than natural. But it will be observed that the membrane is not placed towards the inner or outer angle of the eye, the former of which more especially is the usual seat of pterygium; that, instead of its shape being triangular, like this diseased change, it occupies fully one-half of the exposed part of the globe, one-half of the cornea as well as of the sclerotic, and that this half is the lower; that, instead of being but loosely attached to the coats of the eye just adverted to, it is firmly united to them; and, lastly, that it has a glistening appearance, like that of a cicatrix. But it will further be noticed, that a prolongation of the same fleshy membrane passes from the globe to the inner surface of the lower lid, forming a broad and unnatural bond of union between these parts. These circumstances

prove the case to be one *not* of pterygium, and whilst the fact last alluded to certainly entitles the disease to the appellation of symblepharon—the hard name by which ophthalmologists are pleased to designate adhesion between the globe and the lid—it also leads to the inference that the change in the conjunctiva oculi is the consequence of the same cause which produced this unnatural union. Accordingly, on inquiry it is found that the whole diseased condition in the eye of the boy is the result of mortar having fallen into it five months ago.

The effect of mortar, lime, and mineral acids, applied to the delicate coverings of the eye, is to produce sloughing and inflammation of the parts with which they come into contact. Undiluted, and in sufficient quantity, the parts they touch are killed; and on separation of the sloughs taking place, if these have involved both the globe and the lid, the granulations from the two surfaces inoculate and unite. But this union may take place without having been preceded by actual sloughing of the surfaces; at least I have seen the thickened, seamed state of the conjunctiva oculi the consequence of severe burns, where a mass of flame had suddenly struck the organ, as from the explosion of gunpowder. Immediately after such accidents, I have observed that the cuticular covering was separated from the subjacent part of the conjunctiva on the cornea as well as on the sclerotic, and that the healing of this exposed surface of conjunctiva was as tedious as that of the skin similarly placed from a burn or scald, and that the result has been equally a cicatrized appearance of the part. Should a granulating surface thus produced exist at the same time on the conjunctiva of the sclerotic and lid, the parts might unite without any sloughing having preceded.

In the treatment of the case of this boy, two questions are presented to us:—The expediency of separating the unnatural adhesion between the lid and the globe; the possibility and propriety of removing the opaque membrane from the latter. With regard to the first, it will be noticed that the union is not very close, and that the uniting medium has been somewhat elongated, so as to assume the appearance of a membrane, and that thus the motions of the parts are not materially impeded. The lad can turn the eye in any direction; in some of these, it is true, dragging slightly on the eyelid. The motions of the other eye are not impaired. And when it is considered that in similar circumstances when the parts have been divided, the attempts to maintain them so have almost invariably failed, and that

re-union has taken place, there is but little inducement for us to effect the division in the present case.

With respect to the opaque portion of conjunctiva covering the cornea, as this interfered materially with vision, the successful removal of it would be very desirable. But, in the first place, from the close adhesion of this cicatrized membrane to the subjacent cornea, very different from its loose attachment in cases of pterygium, this could not be easily effected; it would, in fact, require to be shaved off, and then there could be little doubt that the cicatrix to be formed subsequent to its removal would be opaque. On these grounds my present impression is, that not much advantage is likely to arise from any interference with the case, although an operation may be tried without much risk of making matters worse. The boy has only been two days in the house, and I shall reconsider his case.

Among the inflammatory affections of the eye there is no one usually more amenable to treatment than iritis; and there is one remedy more especially so generally successful in the cure of this disease, that it is apt to be too implicitly relied on. When the exhibition of mercury has been followed by its peculiar effects on the system, the symptoms of iritis in the majority of cases subside, and the consequence of the inflammation, provided this has not been of too long standing, are removed. But it is not always that we are able to obtain the peculiar action of mercury on the system by any mode in which it is employed: and when this is obtained, it is not invariably that the symptoms of iritis disappear. Moreover, there are constitutions and conditions of health in which it is not expedient to administer this remedy. Under these various circumstances it is important for us to know and recollect that there are other remedies which occasionally exercise a beneficial effect in arresting the progress of iritis when the more common remedies have failed, or are inappropriate.

An instance of this has been witnessed in the case of Elizabeth Dean, who was admitted with iritis of both eyes, and presenting the ordinary symptoms. The disease had existed a month; there was considerable intolerance of light, and redness of the sclerotic; immoveable iris; pupil of its natural size, but irregular, with lymph in small quantity within each; and vision so impaired that she could not distinguish the largest letters. There was no evidence of syphilis.

Previous to the exhibition of calomel, and along with the application of belladonna,

an active aperient was given, and the patient was cupped on the temples. By these means a diminution of the redness and intolerance of light was obtained. But as the mercury produced no effect on the system, the cupping was repeated at the end of a week.

The abstraction of blood in instances of *iritis* may be resorted to with advantage under different circumstances and views: at first, directly to diminish the violence of the inflammatory action. Again, when the mercury does not act, loss of blood will sometimes, as is well known, be followed by the appearance of this action on the gums. And lastly, I have repeatedly witnessed that the symptoms of *iritis* have persisted even after the system has been fairly brought under the mercurial action; but then that they have given way when cupping was now been resorted to.

In the present case, however, the system resisted the action of mercury, and the disease the remedy and the abstraction of blood. Besides having been twice cupped, leeches were twice applied, and ultimately the patient took two grains of calomel and two of Pil. Hydrag. every four hours, and at the same time to rub in the mercurial ointment, but without any effect on the mouth or on the *iritis*.

Under these circumstances, spirit of turpentine, as recommended by Mr. Hugh Carmichael, was given in doses of a drachm, in emulsion, three times a day. The effect of this was very marked, for in two days the redness had greatly diminished, and in a week the symptoms of active inflammation had wholly subsided, leaving irregularity of the pupil, and points of adhesion, but with the vision restored. My experience of the utility of turpentine is but limited, and I have not seen a case where its beneficial effects were so striking as in the present one.

One objection to the remedy, where it might be thought advisable, is the difficulty or even impossibility of some stomachs retaining it. Dean had, at a subsequent period, a trifling relapse; and then, on again trying the turpentine, it had become so nauseous to her that she could hardly be induced to take it, and when she did it was rejected. Fortunately the symptoms yielded to cupping and to tartarized antimony taken internally.

During the time Elizabeth Dean was under treatment, there was in the adjoining ward an example of another affection of the eye which was benefited by a remedy occasionally useful. I allude to iodide of potassium in chronic *corneitis*.

Adelaide Neves, æt. 9, was admitted on account of a phagedenic ulcer, of the size

of a crown-piece, seated on the fore-arm near the elbow. The surface of the ulcer was pulpy, of a yellow colour, interspersed with red points; the surrounding margin of skin was of a fiery red, with intolerable pain. The cornea of the left eye was generally hazy, and in parts slightly clouded, apparently from effusion into its texture. A zone of minute red vessels occupied the sclerotic all round the cornea, and there was slight increased sensibility to light. The child had a peculiar huskiness of voice, which, with a cachectic appearance, and the character of the sore, led to the suspicion of some taint being present in the system; but this could not be substantiated. The sore had existed in a milder form for some months; the voice became affected soon after its first occurrence; the affection of the eye had been added within the last few weeks.

In the treatment of phagedenic sore with the characters here presented to us, and with pain so excessive, opium is the most efficient agent in obtaining immediate relief and improvement; accordingly, two grains and a half of the compound soap pill were given night and morning; and lint, wetted with a lotion composed of equal parts of liquor opii sedativus and water, was kept applied to the sore; and in two days afterwards there was associated with these compound decoction of sarsaparilla, with the extract; to which were added meat and beer. The result of this treatment was, that the girl obtained rest at night—that the severe pain in the ulcer gradually ceased—that its surface lost its foul character, and assumed in the course of a week that of a granulating sore. Three grains of the iodide of potassium were now added to each dose of sarsaparilla given three times a day. In ten days from this time the redness of the sclerotic had disappeared, the cornea itself being somewhat clearer; and under the continued use of these remedies (for the opium had been omitted) the eye has recovered its natural appearance, with the exception of a trifling haziness, of very limited extent, in the centre of the cornea. The patient is still under treatment, and this may perhaps eventually disappear. The voice has likewise recovered its natural tone.

As a general rule, mercury is to be preferred, and is most to be depended upon in chronic *corneitis*; but the existence of phagedena, and the state of the constitution, precluded its employment in the present case. I attribute the improvement in the eye to the iodide of potassium, which has at times proved serviceable in similar cases; yet as it was here associated with sarsaparilla and good diet, and as

these means contribute so materially to the removal of that cachectic state of system, or feeble state of the general health, with which chronic cornitis is so often connected, it may not, perhaps, be entitled to the chief merit as regards the removal of the cornitis.

Whilst these cases were under treatment you also witnessed an example of the advantages occasionally derived from appropriate treatment in diseases of another of the organs of sense—viz. the ear.

Like the eye, the ear is a complex organ, and imperfection of its functions may depend on disease seated in very different parts: in the external auditory passage, the tympanum, or the internal ear. Consulted as to the cause of distress, our attention is first directed to ascertain whether this does not originate in the first-mentioned part, where it may be produced by a variety of diseased conditions. It may depend upon an accumulation of wax—on inflammation and swelling of the parietes of the passage—on inflammation with puriform secretion—on ulceration and granulation—on true polypus—on inflammation and thickening of the tympanum. Then it may arise from disease within the tympanum, with or without perforation of the membrane—with or without caries of the temporal bone, &c. &c.

In examining the auditory passage, of course we avail ourselves of all the advantages of good light, and, if possible, place the patient so that the rays of the sun may fall directly into it. Additional and great facilities for ascertaining the state of the bottom of this passage, and of the membrana tympani, are obtained by the employment of the speculum auris; for although, in many cases where the passage is wide, and without any lateral projections, we can view the whole extent of these parts without such aid, in numerous cases we cannot do so; and then the speculum, by making the passage straight, and enabling us to dilate it (a mere trifle, it is true), affords us the advantage of a more satisfactory examination.

Thomas Parker, æt. 19, was admitted January 28th, with ulcer of the leg. He was deaf, and his countenance was characteristic of that infirmity. On an accurate examination of the degree to which this sense was impaired, a watch was employed, the ticking of which can be heard at the distance of 20 feet. Parker could not recognize it with his left ear further off than five inches; with the *right*, not further than nineteen. There was no redness, swelling, or rawness, of the parietes of the

external meatus. Not the slightest appearance of wax in the left, and but a very trifling in the right ear. The membrana tympani in each was gone; the cavity of the tympanum in both was filled with a milky secretion, devoid of offensive odour. This having been in some degree removed by syringing the parts, the lining membrane of the tympanum was seen to be more tumid and redder than natural. The patient had been deaf since he was a child; he had always had more or less discharge from his ears, and had been told that some bones had come away. Repeated blistering, and a variety of injections, had been ineffectually tried by him.

Besides the destruction of the membrana tympani, and loss of the bones of the ear, the chief existing morbid action seemed to be seated in the mucous membrane of that cavity itself, unconnected with disease of the temporal bone.

With the view of correcting this, a solution of the acetate of lead—six grains to the ounce of water—was ordered to be dropped into the ear twice daily, and the parts to be syringed with it once daily. Under this treatment the improvement was unexpectedly rapid. In five days the hearing distance of the left ear had increased from five inches to two feet ten inches; in the right, from nineteen inches to seven feet five inches; and (without taking the intermediate periods) in three weeks, in the left ear, to fifteen feet; and in the right, to eighteen. Long previous to this, however, he was quite able to take part in conversation, and his countenance had assumed an expression of intelligence, most singularly contrasting with its former dulness and apparent stupidity. The discharge now ceased, and the lining of the cavity of the tympanum had lost that swollen and pulpy appearance it had previously presented. And, probably connected with these changes, the patient was now able to cause air to pass from the throat out of the external ear, which in the first instance he could not do.

The acetate of lead is a safer application to the ear than the more powerful astringents; and the present case shews its beneficial effects in remedying a diseased state of the mucous membrane of the cavity of the tympanum. This diseased state removed, hearing was restored to a degree which, perhaps, you might not have expected, if you previously supposed the existence of the membrana tympani absolutely essential for hearing.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

April 9, 1839.

SIR B. BRODIE, BART. PRESIDENT, IN THE CHAIR.

A case of Enlargement from Encephaloid and Melanoid Disease of the Prostate Gland in a Child of five years old. By RICHARD A. STAFFORD, Esq. Surgeon to the St. Marylebone Infirmary.

A PREPARATION from the museum of St. Bartholomew's Hospital was shewn in illustration of the paper, exhibiting an enlargement of the prostate gland in the child in question, to the size of a large walnut. There was no disease of the kidneys.

Memoirs on some Principles of Pathology in the Nervous System. By MARSHALL HALL, M.D., F.R.S.L. & E., &c.

MEMOIR I.—ON THE CONDITION OF THE MUSCULAR IRRITABILITY IN PARALYTIC LIMBS.

There has been much discrepancy of opinion amongst physiologists and practitioners on the points treated of in this memoir. Prochaska, Nysten, and Le Gallois, stating that the muscular irritability is undiminished; Professor Müller and Dr. Sticker, that it is not only diminished, but annihilated.

The author having quoted these opinions proceeds to state his own, and to reconcile the prevailing apparent contradiction. He shews that an error has arisen from taking the term paralysis in too general a sense, and proposes to make a specific distinction between those cases in which the power of the cerebrum merely is removed; or of *cerebral paralysis*, and those in which the power of the spinal marrow is removed also; or of *spinal paralysis*. In order to accomplish this more completely than has been done before, he has, in a figure which accompanies his paper, drawn lines, in any point of which disease may be supposed to occur, and which he proposes to designate *lines of separation*. Of these, certain lines separate the influence of the cerebrum, and are the seat of cerebral paralysis; while others separate that of the spinal marrow, and are the seat of spinal paralysis. The figure is necessary to make this perfectly distinct.

The author then proceeds to state, that in every case of mere cerebral paralysis the irritability of the muscular fibre is not only not annihilated, not only undiminished, but usually greatly augmented—a fact previously unknown and unsuspected.

Whereas, in every case of spinal paralysis, the irritability of the muscular fibre is gradually lost, and eventually perhaps annihilated.

The application which these facts have to physiology and practice are principally these:—The spinal marrow, exclusively of the cerebrum, is proved to be the source of the irritability of the muscular fibre: the cerebrum, so far from being so, is an exhauster of this power. In dubious cases, augmented irritability proves that the disease is cerebral paralysis—diminished irritability, that it is *spinal* paralysis. The principle, therefore, becomes a source of *diagnosis*, of the importance of which it is needless to speak.

The same principles enable us to account for the fact, that strychnine, given in certain cases of paralysis, affects first and principally the paralytic limbs. But they lead to the correction of an erroneous generalization of this fact by M. Fouquier, for it is true of cerebral paralysis, in which the irritability of the muscular fibre is augmented only, and not of spinal paralysis, in which that irritability is diminished. The strychnine seems to act on the spinal marrow, and along the motor nerves, upon the muscular fibre, and more, of course, upon those muscles whose irritability is augmented or unimpaired, and therefore, most upon the paralytic limbs in cerebral paralysis, and upon the healthy limbs in spinal paralysis.

The author next explains the action of motion, of certain acts of respiration, as yawning, and of the principle of tone, upon the paralytic limb, in cerebral hemiplegia, whilst the healthy limbs are comparatively little affected.

These points are established by a series of physiological experiments, and clinical observations or cases. The galvanic trough is used as the test of irritability, and consequently as a means of diagnosis.

ROYAL INSTITUTION.

March 8th, 1839.

Mr. Brayley on the Comparative Influence of Heat and Gravitation in regulating the Density of the Atmosphere.

THE lecturer introduced his subject with a concise account of the dynamical and statical properties of atmospheric air—that most important agent in all mechanical and vital processes. He explained experimentally the amount of pressure exercised by this medium on all surfaces, by exhausting a tin vessel over an air-pump, when its sides were forced in by the incumbent weight. He satisfactorily ex-

plained the nature of the Torricellian vacuum, and the truth of the highly important fact, that the weight of a column of mercury thirty inches high is equal to that of a column of the atmospheric air extending to its whole height. The weight of such a column being equal to the weight of mercury contained in the barometer, and counterbalancing it, and the proportion of weight likewise being known between equal bulks of air and mercury, it will be easy to find the height of such a column, and consequently of the atmosphere itself. Thus the height of a homogeneous atmosphere would be about five miles and a quarter. But the prevailing notion has ever been, that the air, from its elasticity, would diminish in density in the direct ratio of its distance from the earth's surface, and that, consequently, if the actual atmosphere could be divided into strata of an inch thick, each stratum would be less and less dense as we approach the top of the atmosphere.

The existence of a definite limit to the atmosphere was first conceived by Kepler, in whose fertile and original mind the seeds of so many great discoveries were developed; and he sought to determine its elevation by means of the duration of the twilight. By an ingenious and interesting process, which writers on astronomy explain, he convinced himself that its height was between forty and fifty miles.

Dr. Wollaston says that, from the law of the elasticity of the atmosphere which prevails within certain limits, we know the degrees of rarity corresponding to different elevations from the earth's surface; and if we admit that air has been rarified so as to sustain only one-hundredth part of an inch of barometrical pressure, and that this measure has afforded a true estimate of its rarity, we should infer from the law that it extends to the height of forty miles, with properties yet unimpaired by extreme rarefaction. Beyond this limit we are left to conjecture.

Mr. Ivory says, if the divisibility of matter be infinite, so must the extent of our atmosphere; for if the density be throughout as the compressing force, then must a stratum of given thickness at every height be compressed by a superincumbent atmosphere, bearing a constant ratio to its own weight, whatever be its distance from the earth. But if air consist of any ultimate particles no longer divisible, then must expansion of the medium composed of them cease at that distance where the force of gravity downwards upon a single particle is equal to the resistance arising from the repulsive force of the medium.

Mr. Faraday observes, that every expansion is productive of cold, and every new degree of cold must diminish the

elastic force of a given volume of atmosphere, gravity continuing to act with nearly the same energy, while the elastic force of the air is continually diminished. These two forces will at length become equivalent, and will counterbalance one another, which is all that is necessary to imposing a limit to the extent of the atmosphere. Mr. Brayley canvassed at some length the views regarding this subject advanced by Wollaston, Ivory, Faraday, Gay-Lussac, Thenard, and others; and taking the mean of their several calculations, he estimated the height of the atmosphere at about forty-five miles. Pailsson entertained a notion that the upper strata of the atmosphere were rendered denser through the operation of cold; and this philosopher went so far as to suppose that the uppermost stratum might even be liquid. Mr. Brayley has adopted a modification of this gentleman's theory, and illustrated on this occasion his views by a very satisfactory diagram. The atmosphere is represented as divided into a series of horizontal strata, and these strata as gradually diminishing in density, in obedience to the diminished force of gravitation, up to a certain point; but that afterwards the diminishing temperature, or the increasing cold, produces condensation. Mr. Brayley contended that this result must take place, from the balance of the forces of gravitation and temperature; and he illustrated his meaning by an experiment with Dr. Wollaston's beautiful *cryophorus*. The condensation of vapour may be effected not only by decrease of temperature, but by increase of pressure. In Dr. Wollaston's *cryophorus*, the force of the vapour is so much reduced by the cold applied to one extremity of the instrument, as speedily to produce congelation at the other, by the rapidity of the consequent evaporation. This process, says Mr. Brayley, is a representation of what is going on in the atmosphere. In the *cryophorus* ice is produced in one bulb, by the rapid evaporation excited by the application of cold at the other. Here we have vapour formed from fluid, first expanding, and then contracting into the fluid and even solid state. There must be a point in the course of the transition of this vapour at which it reaches its highest expansibility, and after which it gradually contracts. Such a point also exists in the atmospheric coverlet of the globe. Mr. Brayley entered into extensive astronomical inquiries to prove the truth of this proposition, and particularly referred to the observations of Sir John Herschel on Halley's comet. The telescopic appearance of this body was represented by drawings, in which the nucleus is shewn surrounded by a luminous halo; immediately

embracing this is an opaque space, which is again involved by a luminous ring. This appearance was explained by Mr. Brayley according to his theory. He supposed—1. that the immediate luminous part is due to the refraction of the sun's light by the atmosphere; 2. that the opacity is due to the great attenuation of the atmosphere which succeeds, and deprives it of its refractive power; and 3. that the subsequent luminosity is reproduced by the condensation of the atmosphere, through the influence of the cold, to such a degree that its refraction is restored.

Mr. Brayley finally furnished the meeting with ingenious explanations, tending to reconcile his views with the numerous astronomical and meteorological facts which have been established by induction.

PHYSICAL SOCIETY, GUY'S HOSPITAL.

April 6, 1839.

DR. BABINGTON, F.R.S. IN THE CHAIR.

Cases of Gangrene; with Remarks.

MR. FRANCE read two cases of gangrene.

CASE I.—John Donovan, æt. 24, was admitted June 2d, 1837, into Luke's ward, under the care of Mr. Key. He was a man of middle height, rather slight make, dark hair and eyes, of florid complexion, and was, when admitted, in a somewhat depressed condition; his general appearance was not very cachectic; he was very deaf, having five years previously been attacked with inflammation in both ears, which had resulted in permanent detriment to their functions, notwithstanding the use of active measures in the treatment; his trade was that of a combmaker; lately he had been but scantily fed; his feet had been ill-defended from wet, and cramped in tight shoes. On admission, the pulse was frequent and feeble; respiration natural; skin cool and perspirable; appetite good; some thirst and restlessness were present. The affection of his feet was accompanied by a little pain; there was no tumefaction nor heat about the ankles or toes; the latter, on the contrary, were below the natural temperature; they were of a dark leaden hue, with vesications here and there, especially on the left great toe; some red lines were visible, ramifying from the ankle to the great toe of the right foot.

Ordered—Infusion of Serpentry, with Sulphuric Ether, thrice a day.

June 3d.—Pulse 104, with more power; tongue dry in the centre, and at the tip;

thirst and restlessness continue; he has been slightly delirious in the night.

Mist. Salin. c. Sp. Ether. Nitrici ter die.

5th.—Face flushed; skin hot and dry; tongue brown and dry; thirst remains; pulse 112, jerking; bowels open.

Cataplasma lini et perstet.

6th.—Sleep has been disturbed by pain in the toes; pulse 116; tongue moister; less thirst; the slough of left great toe is separating.

14th.—Pulse 112, feeble; respiration normal. There is a line of separation exhibited on most of the toes; pain on exposure still very great. The tincture of benzoin was now used as a local application.

It was not, however, till October that cicatrization was complete after the separation of the extreme phalanges. At this time his general health was much improved, and he was gaining flesh; and on the 24th of October he was discharged from the hospital, his feet being mutilated by the loss of the distal phalanges of most of his toes.

CASE II.—Wm. Reynolds, æt. 33, bearing the marks of a stout and muscular frame, though now somewhat anemiated by confinement and sickness, was a policeman in the winter of 1837-8, and was compelled, in the prosecution of his duty, to be frequently and for many consecutive hours exposed to the inclemency of that very severe season, while the frost was intense and protracted, and the snow often of several inches depth. He was called upon during this period to render his assistance at a fire, and in doing which he found himself in the utmost peril; and to the excessive terror hereby occasioned, he attributes the supervention of epileptic fits, with which he was about this time attacked. From November in last to February in the present year, he has been confined by this cause, for the paroxysms seem to have been very violent, and nearly incessant, and to have very considerably impaired his intellect. He was not reinstated in his mental faculties until February, having in the meantime been removed into the country; and in a week or two afterwards the fits likewise finally ceased. It was now noticed that his toes were becoming black and gangrenous. This affection extended, notwithstanding every endeavour to arrest its progress, until the left foot was removed at the central joint of the tarsus, and the right leg was deadened about one-third up. In this state he was brought to Guy's Hospital, on the 6th March, 1839, and immediately admitted. His general condition was as follows:—The heart's action irregular; the pulse quick, small, and feeble; tongue morbidly injected and clean; skin cool;

bowels confined; his manner denoted considerable cerebral excitement; he was peculiarly hurried and agitated, very loquacious, and sometimes incoherent; he complained of much indistinctness of vision, more particularly in the morning and earlier part of the day. On examination, no evidence was found of organic disease of the heart or arteries. The gangrene had not been ushered in by pain, as would have been the case were it the consequence of arteritis or ossification of the vessels; he had not, to his knowledge, partaken of unsound bread or other unwholesome food.

The treatment adopted has produced the best effects, for under it the patient has gained vigour and strength, and his constitution has been enabled to resist the further encroachments of the disease. He was ordered on the day of admission Morphine Murialis, gr. ss. o. n.; 6 oz. of wine, a pint of porter, and meat diet daily. To the gangrenous parts were applied linseed and poppy poultices, succeeded on March 11, by a lime-water and opium application. On the 15th March, quinine was added.

The general health under this management has been materially promoted, and the separation of the mortified portions been accomplished. The last bonds between the living and dead—that is to say, the bones of the left leg—were divided by the saw on the 20th March. The appearance of the stump was healthy, presenting that raw and indolently granulating aspect which is usually seen after the casting-off of a frost-bitten extremity. At the present date, April 6, cicatrization is progressing most favourably.

In making a few comments on these cases, Mr. France took occasion briefly to review the grounds upon which some of the theories to account for gangrene are advocated, and expressed his own opinion that, in the majority of instances, it was to be ascribed essentially to arrest of the circulation in, and deficient supply of blood to, the affected parts. This opinion was supported by several ingenious illustrations and arguments; and the discussion in consequence naturally took that turn. Dr. Borland, Mr. Cock, Dr. Hughes, Mr. Iliff, Dr. Ashwell, and Mr. Greenwood, were the principal speakers; and although many valuable remarks fell from these gentlemen, it did not appear to us that any decisive conclusion was arrived at upon the interesting point of pathology above alluded to.

When the time for adjournment had fully passed, the usual vote of thanks was offered to Mr. France, for his obliging communication, and the meeting adjourned.

At next meeting, April 20, Mr. Branshy Cooper in the Chair, the subject of Syphilitic Iritis will be brought forward by Mr. Menzies.

BOOKS RECEIVED FOR REVIEW.

An Address to the Inhabitants of Bath and its Vicinity respecting the efficacy of Vaccination, and the Causes which prevent the Extinction of Small-Pox in this Country. By Conway Edwards, M.R.C.S. Surgeon, Bathaston; Author of "A Treatise on the Bladud Spa Water."

Medical Portrait Gallery. To be continued monthly. By Thomas Pettigrew, F.R.S. &c. &c. No. 13, containing Boerhaave and Mr. Travers.

LECTURES
ON THE
CHEMICAL HISTORY, PATHOLOGY, AND
MEDICAL TREATMENT
OF
CALCULUS,
AND THE VARIOUS DISORDERS OF THE
URINARY SYSTEM.

By DR. VENABLES.

Diuresis saccharina—continued.

THIRST to an insatiable degree is a prevailing symptom in diabetes. The draughts upon the blood for water voided as urine are excessive; for instance, twenty-four pints was the average daily discharge in the case before alluded to: now—

$24 \div 8 = 3$ gallons,

the quantity of water daily evacuated from the system by the kidneys. Now this water must be furnished from the serum of the blood, and the consequence must be to deprive the blood of its normal proportion of water. Wherever this takes place, nature prompts the animal to repair the loss by exciting thirst, probably one of the most distressing and intolerable of sensations, and to be allayed only by the ingestion of fluids: of these, pure water is the most effectual agent for this purpose, and therefore we find that those who are tormented by thirst in any of its modifications, betake themselves to this wholesome beverage, as affording the most effectual and satisfactory relief.

In the enumeration of the symptoms, a harsh, dry, and unspirable state of skin was represented as an associate or concomitant of diabetes, and, indeed, in all forms and varieties of the complaint, pre-

vails to an extent more or less. This may be accounted for upon two principles. If the insensible transpiration be suppressed, a harsh and rough state of skin is almost invariably the result. When so much watery fluid is passed off by the kidneys, it is evident, in a corresponding ratio, cutaneous transpiration will be suppressed; and hence the harsh, dry, and rough state of skin. It has still further been observed, that in some cases upwards of thirty pints, or three gallons and three quarts of urine, have been voided daily for weeks, or even months, in succession. In such cases the quantity of urine, and solid matter contained in it, have been said to exceed by more than double the whole of the ingesta; and physiologists have puzzled themselves not a little to explain this difficulty, and reconcile the phenomena. Many, however, doubt the facts; but still they are too well attested, and too consistent with what may be observed daily, to justify such a summary mode of dissent, more especially as the difficulties can be explained upon known and admitted physiological phenomena.

The skin, as well as being an organ of transpiration, is also one of absorption; but in all probability both functions are not going on at one and the same moment of time; indeed, they do not seem to be actions simultaneously compatible in the same organ. We also know that if insensible perspiration be checked by artificial means, a flow of urine is an immediate consequence. Thus we account for the flow of urine if the cutaneous functions be checked by exposure to cold,—as, for instance, happens to those who, having prepared for a plunge into the sea, the mere exposure of the skin by stripping off the clothing is attended with an immediate call to evacuate the bladder. But the person who has responded to the call, on the immersion of the body into the water, after a few minutes—sometimes

even seconds—feels himself called upon again to evacuate the bladder. Now whence can this second call arise; it must undoubtedly be owing to the skin absorbing a large proportion of the surrounding medium, and inundating with it the blood, when the kidneys in turn set to work to relieve it from the superfluous burthen.

It may perhaps be objected that, as the suppression of perspiration in the first instance, by exposure to the cool atmosphere, excited to urinary evacuation, that the succeeding uresis depended upon a similar cause to the first—namely, the operation of a still cooler medium upon the functions of the skin; that is, cutaneous perspiration being still suppressed, what ought to pass off by this organ now passes off by the kidney. But even allowing the due weight to this objection, when we consider the rapidity and the frequency with which the bladder is evacuated under such circumstances, and also the very much larger quantity voided in a given time, as compared with what would be voided under ordinary circumstances in an equal time, we must admit that the difference cannot be explained without calling to our aid the principle of cutaneous absorption, and admitting the inundation of the blood with watery fluid through this medium. But in still further confirmation of this principle, it may be urged that the same phenomena, to an equal or even still greater extent, takes place if the person, instead of cold water, immerse himself in a warm bath. These are facts which will be readily admitted by all who have any personal experience upon these subjects. But lastly, and still more effectually, perhaps, it may be urged, that the immersion of a portion only of the surface—the feet and legs, for instance, while the functions of the rest of the cuticular surface remain as under ordinary circumstances—is attended with evacuation of the bladder to an extent irreconcilable except upon the principle of cutaneous absorption, as above depicted.

Now admitting these doctrines, we can readily explain the excess of the urine over the ingesta. The atmosphere is at all times more or less loaded with watery vapour; and consequently, when the system requires it, we have no reason to suppose that the skin will be found less ready, or less active, than the other tissues, in attending to and supplying the wants of the system. Consequently we can readily explain the excess of water over the fluids ingested, evacuated from the bladder by the absorption of watery vapour from the atmosphere by the skin. Part also must be attributed to the solution and absorption of the animal tissues themselves, and

their conveyance into the blood, and ultimate discharge from the system through the kidneys. This, too, will serve to explain the extraordinary emaciation which sometimes is observed in diabetes. The tissues are absorbed in preternatural quantity, and evacuated with the urine, while nature otherwise disposes of the alimentary matters which should supply the waste, by the suppression or interruption of the assimilating functions, and directing the assimilative matters to the kidneys, whence they are ejected from the body. Nor is this to be objected as a fault, because the digestive functions appear to be in error; and consequently a healthy assimilative matter is not prepared; and the laws which govern the animal economy are such as will mostly refuse to submit the tissues to the consequences, and hence a morbid and perhaps most pernicious commixture with the blood is refused a habitation in the system, and is therefore directed to the kidneys, to be by them immediately evacuated from the system.

It is rather a singular coincidence, too, that persons liable to urinary diseases are also very frequently subject to cutaneous affections. This was the case with respect to Mr. P. He had previously suffered most severely and extensively from cutaneous eruptions of an impetiginous character, and for which he could obtain no relief, till, on application to Mr. Plumb, he was completely cured by a lotion of hydrocyanic acid in a large proportion of water. The female whose case also I have mentioned as one of saccharine diabetes, was often troubled with psoriasis, and, in many of the cases of excess of urea, cutaneous affections of various descriptions either coexist or have prevailed at some earlier period.

It is matter of curious speculation how long such diseases may have prevailed, or what length of time they may have lain in this, as it were, dormant or at least undetected state. That Mr. P. had suffered, at a much earlier period of life, from disease of the urinary system, came to my knowledge on making more strict inquiries. He gave me to understand, that about eighteen or twenty years before the time of my seeing him, he suffered from very great distress in the urinary system, and an incapability of passing water. The disease under which he laboured was supposed to be stone in the bladder, and his distress and sufferings greatly increasing, it was determined he should proceed to London to be operated upon. When on his journey, at Ingatestone, where the coach stopped for breakfast, he happened to meet with a friend, formerly a surgeon in the navy; and, on his explaining to him the object of his journey,

this gentleman made several inquiries; upon which he declared his conviction that there was no calculus, and that if he would but follow his advice, he would soon be perfectly well. This was consented to, and he was recommended an infusion of some *vegetable*; the name or nature of which, however, I could never learn nor distinctly trace, as he could not recollect it. He complied, however, with the directions of his friend, returned home, adopted the treatment recommended to him, and in less than three weeks had completely recovered, or at least was perfectly relieved from his former misery.

This history is in many respects extremely interesting in a pathological point of view. First, how are we to account for the phenomena? Are we to presume that the sufferings of this patient were chimerical—the mere delirium of a temporary nervous excitement; or was there a substantial physical cause relieved or abated by the means adopted? My own opinion inclines to the latter view. When we connect the existing condition of the urine, the previous sufferings from cutaneous affections, the tendency to gout, we can be at no loss to trace the deeply-rooted urinary affection; and of course we can readily admit the urinary distress so much resembling a calculous affection, as a mere admonitory hint of what probably was about to occur, and which subsequently did actually occur. Secondly, if the table be referred to, it will be seen that, among other characters, a fatty state of the urine is noted; and this occurred frequently, and was noticed by Dr. Prout in one of his communications to me. Now this peculiar fatty matter depends upon tumors within the bladder, of a steatomatous character, by which it is thrown off, and mingled with the urine. I have seen this in several other instances, and have twice had an opportunity of confirming these views by subsequent anatomical examination. Now it is probable that the calculous symptoms in this instance depended upon the morbid condition of the bladder antecedent to the development of the tumor above noticed. Symptoms very closely resembling those of stone prevail in certain morbid conditions of the mucous lining, and, indeed, general structure of the bladder. Thus, I remember the case of a coachmaker, at Witham, in Essex, concerning whom I was consulted; the symptoms closely resembled those of stone in the bladder. He was sounded, but no stone could be found. As I shall have to detail the particulars of this case more fully hereafter, I shall merely observe, that a year or year and half after I was consulted he died; and, on examining the body, a sort of fungous tumor, with a

pouch from fold of the mucous membrane, was found in the bladder, which I believe is now among the preparations in the museum of the Royal College of Physicians.

It has been already stated, that in all probability a strong predisposition to diabetes exists in many cases. Predisposition to disease may be considered as of two kinds—*hereditary* and *acquired*. Hereditary is transmitted to posterity from their ancestors. Persons who suffer from hereditary diseases must be supposed to have the peculiar predisposition infused from the moment of conception, otherwise it must be ranged under the head of acquired or accidental. Acquired predisposition arises from the operation of accidental or otherwise adventitious agencies, and which, by sufficient care and foresight, might have been avoided. Hence there is a material difference between the two; as the former is absolutely inevitable, whereas the latter is not necessarily so. But in what consists predisposition? It is difficult to conceive any state intermediate between health and disease. There are many instances of individuals predisposed to disease, who enjoy a seemingly perfect immunity for a long period: for example, we may refer to gout, to phthisis, and even to many forms of urinary disease. In many cases the predisposition may be rendered a dead letter; that is, kept dormant, and even finally eradicated; so that persons born with a strong predisposition to peculiar diseases may pass through life without any development; or the anatomical condition even which constitutes the predisposition may, in the milder cases, be even wholly eradicated. In acquired predisposition, we find the causes in those irregularities and abuses, which have been depicted under the head causes. It may, perhaps, here be inquired whether any combination of exciting causes could give rise to diabetes, without previous or co-existing predisposition. There can be little doubt, however, that there are causes, the application, at least the continued application, of which will fully establish this disease under some of its modifications; and yet it is probable that these causes operate in the first instance by inducing what we term predisposition, and subsequently the actual disease.

Immediate cause.—It is usual with medical writers to comprehend under the causes the *proximate*; and perhaps no part of the history of diseases has given rise to more controversy than the nature of this cause. It has been defined as follows:—"Causa proxima est illa quæ præsens morbum facit,

* Gregory's Conspect. Med. Theoretic. cap. I, xxxviii.

sublata tollit, mutata mutat *." In fact, the proximate cause of a disease may be regarded as the *real essence* of the disease—that is, that peculiar something which constitutes it what it is, and nothing else. This it is evident we know not, nor probably are our faculties such as that we could comprehend it. But it has been the practice to consider the word proximate cause as the real essence, and yet to dispute of it as the mere nominal, which is merely the work of the human understanding, and quite distinct. It therefore appears to me advisable to proscribe this term altogether, and to introduce in its place a term less likely to excite chimerical ideas and useless controversy.

The great error in the economy is the existence of sugar in the urine. Now how comes it that sugar—a principle containing no nitrogen whatever—should not only appear in the urine, but absolutely supply the deficiency of urea—a principle containing a very large proportion of nitrogen? It is remarkable, however, that although the existence of sugar in the urine in small proportion is not an unusual occurrence in certain cases of dyspepsia, gout, &c.* yet I believe it mostly happens that in such cases, during the absence of sugar, its alternating principle, urea, is always found in excess. Therefore it would appear that there is some specific connexion between these two principles. Dr. Prout attributes it to a suspension of the essential merorganizing changes, while the re-reducing power of the stomach goes on even more rapidly than in health; consequently the food is more quickly dissolved and absorbed. But still the merorganizing processes either not taking place at all, or but imperfectly, the products are unfit for the animal economy, and therefore are ejected in self-defence.

Upon these principles it is evident that the digestive organs are the principal seat of error, in consequence of which the assimilative functions do not go on. What, then, is the result?—a morbid condition of the blood. It has been lately asserted that sugar has been discovered in the blood of diabetic patients. It is well known that physiologists and chemists, till lately, had searched, and searched in vain, for sugar in the blood. I have also searched for it in the blood of diabetic patients, but, I must confess, without success. Indeed, it was while engaged in researches of this sort, that it occurred to me to modify the sulphuric acid test with a view to render it more available as a trial test; but although indirect evidences occasionally occur, from which the presence of sugar

might be inferred, yet I do not consider it either legitimate or safe to assent to the presence of sugar either in the blood or the urine without the absolute evolution of the principle itself, and identified by all its characters, sensible, mechanical, and chemical.

Allowing that sugar has been found in the blood of diabetic patients, still we shall be at a loss to account for its presence in this fluid. It is true that sugar forms a part of the diet of man; and it might be supposed that this principle, undecomposed, entered the blood, and passing through the kidneys, appeared in the urine. But a total abstinence from sugar does not in the slightest degree reduce that of the urine*. In a case of diabetes, in which the average specific gravity of the urine was 1046, its taste distinctly saccharine, and the quantity averaging about twelve pints in the twenty-four hours, I at various times interdicted altogether the use of sugar, but yet I did not find either the specific gravity reduced or the sweet taste diminished. Chyle naturally has a sweetish taste, and therefore probably contains sugar. Mr. Brande, during some physiological researches, in which he assisted Sir B. Brodie, had an opportunity of obtaining it in large quantities from both carnivorous and granivorous animals. He states chyle to be an opaque white fluid, of a sweetish saline taste, and of a specific gravity inferior to that of blood: it exhibited a slight alkaline reagency with infusion of violets. On removal from the thoracic duct, it gelatinized spontaneously, and then gradually separated into a finer yellowish white coagulum, and a transparent colourless serum. The coagulum possessed properties resembling the caseous portion of milk, and hence Mr. Brande regards it as a variety of albumen. The serum, when heated, deposited a few flakes of albumen, and when evaporated to dryness afforded a small portion of a substance analogous to the sugar of milk†. Tiedemann and Gmelin found no traces of the substances used as food in an unaltered state in the chyle; they merely found that when the animal had taken butter, the chyle contained an abundance of fatty matter; and in the chyle of one dog which had taken starch they detected sugar.

Dr. Prout made a comparative analysis of the chyle of two dogs; one of which had been fed on vegetable, and the other on animal food, and found the constituents as follow:—

* It may also be observed, that diabetic sugar does not so much resemble cane sugar—the article of diet—but is much more like to that of grapes.

CLINICAL OBSERVATIONS ON FEVER.

BY CHAS. LENDRICK, M.D. T.C.D.

Queen's Professor of the Practice of Medicine
in the School of Physic in Ireland, &c.

[Continued from p. 12.]

Natural tendency to recovery in fever.—Extent to which the bowels ought to be acted upon.—Cooling applications to the head.—Use of James's powder and mercury.—Abstraction of blood.—Leeching the temples.—Opening the temporal artery.—Cold douche.—Blisters.—Rules for treating inflammation combined with typhus.—On the use of stimulants.—Various kinds of wine and malt liquors.

THE tendency of typhus fever, in the great proportion of cases, is to recovery. The bodily debility—the torpor of the faculties—the stupid, vacant, and yet anxious appearance of the countenance—the furred and coated state of the tongue—and the quickness of the pulse, are observed to increase progressively up to a certain period, when these and the other symptoms undergo an amendment; the time of its occurrence varying from the 7th to the 14th day, in the average of instances: yet it is often much later than any thing like a critical change is to be observed, and, in general, the later the period the less marked and obvious is this change. Whatever may be its amount, the recovery of the patient may usually be dated from it. Sometimes, after an amendment, the disease becomes stationary, and then proceeds to increase, as before the crisis took place. This false crisis is among the worst symptoms of typhus fever, and the instances of recovery after such an occurrence are rare.

It may be laid down almost as an aphorism, that extraordinary occurrences in typhus are bad ones. The very worst symptom in the disease is a non-agreement of symptoms. For instance, where with those denoting a severe form of fever, we have a single symptom usually in such cases characterized by morbid alterations, but in the instance before us existing nearly as in the state of health, the prognosis may almost invariably be bad: such, for instance, are complete rati-

ality, or an appetite for solid food, or a regular pulse, or a clean tongue; while the whole course of the disease denotes a case of intense typhus fever. Almost complete inanition, a corpse-like state, with fixed eyes, a hanging jaw, and imperceptible pulse and respiration, were less unfavourable than this, as indicative of the probable result. It is, however, to be borne in mind, that an epidemic often introduces peculiar characters, even in comparatively trivial cases. Thus, of late years, a remarkably slow pulse, sometimes not exceeding 40 in a minute, has been an attendant symptom in many mild cases of fever; and yet one which, some time since, would have been justly looked on as the precursor of a fatal termination. The medical practitioner cannot be too little the slave of authority, or too much on the out-look for those changes in disease by which its characters are varied from time to time.

In the great proportion of cases of fever, the physician, bearing in mind its natural tendency to increase up to a certain period and then to decline, will best consult the patient's welfare by almost restricting his treatment to early confinement to bed (this is the *sine quâ non*), the use of an apartment large and well ventilated, but neither cold nor containing currents of air, and the administration of tepid diluting drinks, whey, &c., or even such as are cold (provided they are desired by the patient, and the skin is not disposed to perspiration). To this treatment ought to be added strict cleanliness, by frequent change of linen and sponging the skin with tepid or cold vinegar and water, according as it is moist or parched; carefully avoiding, however, permanent exposure to damp or the risk of catching cold.

There is often much apprehension in the mind of the medical attendant as to the regularity of the bowels. When, however, we recollect that persons in health, and using stimulating food, preserve that health with a single evacuation from the bowels daily, or even less, why should we consider this or more than this necessary, in a disease characterized by debility and collapse, and in which the ordinary means of nutrition are withdrawn? Yet, strange to say, two or three loose evacua-

tions in the day are often considered, by both doctor and nurse, as not only salutary but indispensable for a safe course of typhus fever. The late Doctor Boyton often remarked, in his clinical lectures at the School of Physic, that he never knew a patient to die with constipated bowels, but numbers of, or at least with, abundant and loose discharges. The general correctness of this observation must be agreed to by every practitioner of experience.

Where, either at the commencement or in the progress of fever, the bowels have been confined for more than a day, with distension or uneasiness of the abdomen, or an increase of febrile symptoms, an evacuation ought of course to be obtained. One of the best medicines for this purpose is the oily draught, or from one to two spoonfuls of good castor-oil, floating in a small cup of coffee. If this should be offensive to the stomach, a rhubarb draught* may be exhibited; preceded, where there is reason to suppose an accumulation in the bowels, by Lady Webster's pills (as described in *Paris's Pharmacologia*), or some other aloetic preparation. By such means the contents of the bowels may be removed, without their being irritated by the production of an unusual secretion. The effects of aloes on the rectum are not injurious, when it is exhibited for so short a time, at least to such a degree as to constitute an objection to its use. The administration of enemata, whether in conjunction with the laxatives just mentioned or independently, possesses the great advantage of freeing the bowels for the time, and of doing no more—that is, of evacuating their existing contents, without causing future diarrhœa.

When the bowels have been once emptied, a single evacuation daily, or that average (such as two stools on each alternate day), will be found quite sufficient; and I should be more apprehensive of a considerable variation above than under this standard. It is not improbable that, as some authors have remarked, diarrhœa in the course of fever may be sometimes attributable to neglecting the due evacuation of the bowels at its commencement: yet, for one such case, ten occur where inseparable mischief is done by early purging.

The moderate evacuation of the bowels at a rate not exceeding one discharge daily, with attention to cleanliness, external fomentation, and diluting drinks, constitute the most successful treatment of fever in the great majority of cases; except, indeed, the occasional use of the

effervescent mixture of citrate of ammonia, or of the citrate in the still and neutralized form, there is generally little else to be done, if the head be not much engaged.

Affections of the brain are, however, such dangerous attendants on fever, that the physician ought always to be on the watch for their occurrence. It is no bad rule, in almost every case of typhus, to shave the head. The mere removal of the hair relieves cerebral symptoms; and if headache be present, a cold lotion ought to be applied. Dr. Osborne prefers, for this purpose, cotton wadding to the cloths generally used; and by this, the evaporation of the fluid and the cooling process are much more readily effected. Cold is sometimes overdone; and when the heat of the scalp is found to have diminished to the usual standard, the lotion should be discontinued. A sensation of deep aching pain in the head is a frequent consequence of lotions being too cold or too long continued. In almost every case where these cold lotions are used, warm fomentations should be applied to the feet, especially if the patient be restless. This application, simple as it is, is a powerful sedative.

I am in the habit of directing the alterative powder used in the Cork-Street Fever Hospital, formed of one grain of calomel and two or three of James's powder. By James's powder I mean the empirical preparation; the imitations in the *Pharmacopœia* being comparatively worthless. The alterative powder is given every night while head symptoms are threatened, up to the period of convalescence. It forms almost the only exception in my treatment to the principle of waiting for symptoms instead of anticipating them. I think it is unquestionably beneficial in its action on the brain. It seldom acts on the bowels, or, if it should, this effect can easily be restrained by the addition of an astringent.

Where, however, there is severe pain in the head, with increased determination of blood—where delirium supervenes, or coma is advancing—a more active use of mercury and antimony becomes necessary, and forms, in fact, our most powerful means of saving the patient. The above medicine must, according to the urgency of circumstances, be repeated three or four times in the day; or it may be requisite to give two grains of calomel* and three of James's powder every third hour, as in *iritis*. With such doses, the action of mercury on the bowels must of course be restrained; and as opium is, from its influence on the brain, generally con-

* *R* Infusi Rhei cum duplo Rheo, unciam; Bicarb. Ammonie, grana decem; Sulph. Magnesie, drachm. = i.—ii. Solve, et fiat haustus. Capiat cum semicuncta succi limonis in actu effervescentiæ et repetatur horâ tertia quâque ad effectum.

* Dr. Law's mode of affecting the mouth by minute doses of calomel, such as a quarter of a grain every hour, is comparatively free from the objection of irritating the bowels.

tra-indicated, the object may be effected by administering the alterative powder in the form of bolus, with the electuary of catechu (prepared without opium) and kino.

In cerebral cases the constitution is often remarkably repugnant to the influence of mercury and antimony. Two more powerful agents in such cases we do not, however, possess; and if we succeed in touching the mouth with the former, and producing a slight nausea with the latter, the patient is generally saved. Keeping these objects in view, the doses or their repetition must be regulated by the discretion of the practitioner. In cases of incipient pneumonia, where, with a crepitus near the base of the lung, we have also loss of respiration at the base, and some of the usual symptoms of this disease—where, in short, the existence of pneumonia is unequivocal,—this treatment ought to form our principal resource.

Mercury and antimony, however, are to be reserved for the above-mentioned cases, where their administration is necessary, or rather indispensable. They are both liable to the serious objection of producing irritation in the stomach and intestines. I never concurred in the hypothesis of gastro-enteritis being the essence of typhus fever; but undoubtedly it is such a frequent attendant, and so dangerous and unmanageable a one, that we cannot be too careful in avoiding any mode of treatment, not otherwise indispensable, which might favour its production; more especially if any of the symptoms which usually announce its invasion, such as nausea, diarrhoea, pain on pressing the epigastrium, or redness of the tongue, should have made their appearance*. For this reason, where antimonials are necessary, I generally prefer James's powder to the tartarized antimony, which produces a more irritating effect on the stomach and bowels.

General blood-letting is rarely practised in Dublin in typhus fever unconnected with local inflammation, the erroneous pathological notions which led to its adoption having long since disappeared here. In cases of undue determination to the head, local bleeding is the mode we usually have recourse to. The medical attendant ought to bear in mind, however, that a florid hue of the countenance, throbbing of the vessels, and some difficulty of respiration, are often merely symptoms of that general excitement which precedes a critical change, or at least an amendment

in fever; and that depletion then is more likely to be injurious than beneficial. This remark was made long since by our fever hospital physicians.

Where pain in the head exists, attended by determination of blood, there can rarely be any injurious effect from the application of a few leeches. On the contrary, the patient will generally find the symptoms relieved and restlessness diminished; and it may, in my opinion, be laid down as a rule in the treatment of fever and most other diseases, that relief from suffering of any kind is always desirable as a means of cure. With this view, where the patient suffers from want of sleep, amendment is accelerated by administering at night a pill of three grains of good extract of hyoscyamus. The use of a larger dose, or of any preparation of opium, is, under such circumstances, a more questionable matter, and will be considered hereafter.

In order to avoid unnecessary annoyance, it will generally be the better way to apply the leeches (six or eight in number) to one temple, to cause the patient to lie on the opposite side, and to place a few folds of clean linen over the leech bites. When the cloth is saturated with blood it may be removed, and the temples lightly bound up: thus the annoyance of steeping is avoided. This is Dr. Osborne's practice. A patient should never be allowed to lie on a bleeding surface. Under particular circumstances an unseen bleeding may constitute a dangerous hæmorrhage.

The loss of a few ounces of blood thus gradually oozing from the temples much relieves cephalic symptoms without exhausting the general strength. On the principle, therefore, of not doing more in fever than is necessary, this mode of abstracting blood ought always to precede more energetic measures of the kind. If, however, the symptoms should continue unrelieved, or delirium supervene, a more active abstraction of blood is requisite. No mode is more powerful, or, as far as an efficient removal of blood without constitutional exhaustion is concerned, more advantageous, than temporal arteriotomy. Unfortunately, however, the other consequences are sometimes such as to render its adoption in private practice, unless in a case of great urgency, far from desirable. The object of abstracting arterial blood, and in almost any quantity required, can be attained by cupping the temples. For this purpose good and peculiar apparatus, with dexterity in its use, are indispensable. Adequate directions for the performance of the operation are given by Mr. Hills, in his little treatise on Cupping. The practice of cupping the temple was introduced into our clinical hospital on the recommendation of Dr. Swan, during

* Where these symptoms are not present, the combination of tartar emetic and opium, administered according to the directions of Dr. Graves, affords a useful remedy in the sthenic forms of delirium, as referred to in a subsequent part of these observations.

his pupilage, and who displayed great skill in its performance.

Should pain in the head, with determination of blood continue unabated after cupping the temple, the antimonial and mercurial measures aforementioned should be had recourse to; and in the mean time, if the cupping should have been unsuccessful, blood ought to be abstracted directly from the temporal artery, especially if the pressure of the cupping glass is irksome. The best way to avoid the bad consequences of arteriotomy is to make the incision at least an inch from the zygoma, and directly in the course of the artery—neither across nor obliquely. Secondary hæmorrhage and aneurism are thus less likely to occur, or other parts to be wounded, when a puncture is made, on the failure of the incision to open the vessel. A good lancet is the best instrument for the whole operation; and it ought to be held between two fingers and the thumb, and not merely between the forefinger and thumb, as in ordinary venesection. If the patient be not refractory, the best mode of stopping the bleeding is to cause an assistant to place his finger on the wound for some time till the disposition to bleed cease, and then to apply sticking plaster, a compress, and a triangular handkerchief as a bandage, lightly. If the patient be violent, the bleeding considerable, or professional assistance not likely to be at hand, the better way is to raise the artery on a tenaculum or needle, to cut it across, and then to apply the bandage. In every case the patient ought to lie on the opposite side, so that the wounded temple may be in view, and any disposition to hæmorrhage at once discovered. Lives have been lost from the neglect of this precaution. It would be well, indeed, that all attendants on the sick, and indeed people in general, were aware that the most serious hæmorrhage, even that from a considerable artery, may be kept in check for any required time, and till surgical assistance can be procured, by merely placing a bit of rag over the bleeding point or surface, and gently pressing or rather keeping it in contact by means of one or more fingers, another person relieving the operator if fatigued. It is only necessary that the pressure be unceasing, and of course that the part should not be uncovered even for an instant. This rule applies to all external hæmorrhage, whether from surgical operations, wounds, leech-bites, varicose veins, &c.

Where a patient is violently delirious and intolerant of restraint, I quite concur in the opinion generally acted on here, of allowing every degree of liberty compatible with safety. Cases have occurred of a patient rushing, under such circum-

stances, into the open air, not only without injury, but with advantage; and I should have no objection to permit him, when violently bent on accomplishing his purpose, to go out of the house in fine weather, if properly clothed and attended. It is generally admitted at the present day, that the best and safest way to remove maniacal excitement, is to permit the ebullition to take place, and thus to pass away. In yielding to the wishes of the patient by affording liberty, precautions as to safety must, of course, be adopted, and sufficient attendance provided.

In these cases of violent excitement the cold *douche*, by means of a common cullender on the head, is highly advantageous, and still more so if the patient can be persuaded to sit at the same time in a *semicupium* of warm water, and which is readily formed of a common washing-tub. After an application of this kind, and an indulgence of liberty, sleep is often procured, although absent before. Should it be otherwise, three grains of extract of hyoscyamus should be administered. If the patient continue to be restless, an eighth of a grain of acetate of morphine, with half an ounce of Mindererus's spirit, and six drachms of camphor mixture, ought to be given every four hours till sleep is obtained, and which, in such cases, is generally followed by convalescence. The practitioner should always, however, bear in mind the great susceptibility to the influence of narcotics which exists in typhus fever. In a case* lately in the clinical hospital, narcotism was produced by a dose not equivalent to more than half a grain of opium. A gentleman labouring under typhus, with maniacal excitement, whom I attended many years ago with the late Dr. Cheyne, fell asleep, and convalescence ensued, on the administration of two grains of Dover's powder. Where, however, fever is complicated with delirium tremens, a more active use of opium may be requisite; but even here we ought to feel our way with graduated doses of morphine†, progressively increasing.

It is a good general rule to abstain from the use of blisters during the presence of febrile excitement. It is, indeed, to the stage of coma, or the approach of collapse, that these applications appropriately belong. At a much earlier period, however, of typhus combined with phrenitis, we may have recourse to the tartar emetic ointment, by means of which, applied to the scalp (as the surgeon of our Foundling Hospital, Mr. Creighton, long since remarked), the specific antimonial influence, so beneficial in such cases, is introduced

* It is unnecessary to specify cases where the details are unknown to the reader.

† See note, page 103.

into the constitution, while a powerful external stimulus is established.

It would be to go over nearly a course of lectures on the practice of medicine, to describe all the forms in which local inflammation combines with typhus fever. In short, any of the phlegmasiæ of the viscera may attend on typhus, and that in two modes:—1st. Where the predisposition to such local disease is strong, or the influence of the accessory causes of fever considerable, the inflammatory symptoms are generally simultaneous with, or, indeed, rather precede, the others; and a distinction of the case from one of simple organic inflammation can only be made by observing some of the lurking symptoms of the typhoid affection, which is now masked by those of inflammation, such as the peculiar expression of countenance, petechiæ on the skin, or the (for mere inflammatory disease) unusual loading of the tongue. These distinctions are of the last importance, as, if depletion were had recourse to the full extent that inflammatory symptoms might seem to require, the patient would be irretrievably sunk. It is therefore a good rule to practise blood-letting, on account of inflammatory diseases, cautiously, when typhus is epidemic, or where the patient has been exposed to contagion, even though typhoid symptoms have not yet appeared. 2dly. Symptoms of inflammatory disease do not take place till the secondary period of typhus, or that of reaction or excitement. This reaction is, in typhus fever, often scarcely observable, or it assumes the form of mere congestion; but in some cases it is fully developed, and constitutes local inflammation. A diagnosis from mere inflammatory disease is obviously less difficult in this case than the former, on account of the previous typhoid symptoms.

The following practical rules may, I think, be advantageously adopted in the treatment of organic inflammation, combined with typhus fever:—

1st. To practise blood-letting, or other depletory measures, only to the amount indispensably necessary for the relief of the inflammatory symptoms.

2dly. To remove blood, as far as practicable, at an early period of the case, when its abstraction is most beneficial to the inflammatory and least injurious to the typhoid symptoms.

3dly. To prefer local bleeding, where sufficient for the purpose, to venesection, as producing less exhaustion of the constitutional powers.

4thly. To adopt, where admissible, those measures which are usually found to be auxiliary to blood-letting in inflammatory diseases—such as antimony, where there is no irritation of the stomach and bowels; or digitalis, where there is no tendency to

coma. Thus an unnecessary loss of blood for antiphlogistic purposes may be avoided.

In the ensuing observations as to the use of wine and other stimulants in typhus fever, the cautions as to their administration apply with redoubled force where actual inflammation is combined with typhus, as we have then more serious results than the production of mere excitement to apprehend from their over-administration. These are the really difficult cases of fever to manage, and which task the utmost skill, vigilance, and caution, on the part of the practitioner, whether in the contemporary or alternate use of depletory and stimulant measures. Let him, however, recollect the golden rule, to do with respect to both what is necessary, and no more, and he will have no cause to blame himself for the result, whatever it may be. Sometimes it is requisite to remove blood by local means from the head, or to practise venesection on account of pulmonary inflammation, and also to administer wine to support the general strength the same day.

Coma is frequently the state whereby the excitement of fever changes to collapse. We accordingly have comatose symptoms present in both these stages of the disease, and its treatment partaking of that of both. Thus, while we continue the use of mercury and antimony, and even of local blood-letting from the head, it may be also necessary to apply blisters to the calves of the legs, and mustard cataplasms to the feet, to excite the dormant powers of life, while we endeavour to obtain a derivation from the cerebral circulation. This treatment is especially requisite in what are termed the congestive or apoplectic forms of typhus, when the period of collapse, which often takes place early, has arrived.

The collapse of typhus fever occurs in two modes—suddenly, and often preceded by high excitement or coma; or gradually, as it were by the powers of nature being worn out. The first is the more dangerous, not only in itself, but also as rendering the stimulating treatment, which is indispensable, more precarious. The supervention of gradual collapse may be warded off by meeting the symptoms of debility as they become progressive, by means of light nourishment—such as panada, weak chicken broth, caudle, &c. By thus administering nourishment, and a little wine, on the first accession of symptoms of increasing debility, I have often, I am certain, succeeded in materially lessening the duration of the disease, and the amount of the collapse. Such cases are, however, comparatively of easy treatment: I mean those where we have mere debility to cope with, there is little

difficulty in regulating the amount of stimulus. It is where cerebral congestion, or the dregs of previous excitement, or of inflammation itself, are coexistent with an increasing debility threatening complete collapse, that the utmost circumspection is necessary. Support of some kind is obviously indispensable, and yet, if it be at all overdone, we make matters worse than before.

Nothing proves more, in such cases, the susceptibility of the constitution to undue stimulus than the return of febrile excitement, or even a very small portion of any animal preparation or solid food being administered. The injurious consequences of these is greater, as being more permanent than the effects of wine itself. It is the general practice in the clinical hospital of the School of Physic, on the supervention of collapse suddenly, or where much excitement has preceded it, to exhibit what is termed the cardiac mixture (a combination of camphor, Hoffman's ether, and ammonia), and to resort to more active stimulus only on the failure of this to preserve the strength of the system. Should excitement be produced by the cardiac mixture, the physician learns that, *à fortiori*, stimulus by means of wine and nourishment would have proved prejudicial.

Musk is generally considered as especially applicable to the spasmodic symptoms of fever, such as subsultus tendinum, rigid contraction of the muscles, tendency to convulsive contractions, &c. I think its beneficial effects are almost equally remarkable in comatose cases. An experienced nurse once remarked to me, that "it cleared the head;" and, undoubtedly, we often observe a diminution of stupor, and a return of consciousness and of a susceptibility to external impressions, consequent on its use. Musk must, however, be of the very best quality. The administration of an inferior article (generally known from the absence of the peculiar odour in the patient's apartment) is loss of time, money, and life. I generally prefer the exhibition of musk in the form of bolus, from fifteen grains to half a drachm daily, mixed with conserve of roses and syrup—a dose of the cardiac mixture being given at the same time.

Wine, says Dr. Buchan, in his *Domestic Medicine*, is worth all the other cordial medicines put together; and the Doctor says truly: as also in his subsequent remark, that in order to bear out his encomium, the wine must be "sound and good." For this reason I think that wherever economy is an object, Cape Madeira is entitled to a decided preference, inasmuch as the best Cape wine is cheaper than the worst port or sherry. Therefore

if price is to be considered, let Cape Madeira of the best quality be preferred, as the soundest, although perhaps not the most agreeable, wine*. In the upper ranks of life, the selection of the quality of wine is generally regulated by the taste of the patient. One wine will often agree when another does not. All may be brought to the same strength by more or less dilution with water. In general when we try wine first, or where the patient is a female or under puberty, claret, sauterne, or the light Rhenish wines (if there be no tendency to diarrhoea), are to be preferred. Persons of luxurious habits are often more benefited by Madeira than any other wine, especially if the weaker kinds have failed as a stimulus. Champagne (if genuine) is especially adapted to what are called putrid cases, with great thirst, black tongue, fetid discharges, and livid petechiæ. Good port is an excellent average wine. It ought to be diluted with water at first.

It is, however, of more importance to determine the time for having recourse to wine, and the quantity to be used, than its quality (provided always that Dr. Buchan's conditions be complied with). In private practice, wine is given in fever and other cases as a restorative on convalescence taking place, just as it is used as a luxury during health. What, however, I have now to do with, is the *necessary* use of wine as a medicine, during the collapse of fever, or on its approach.

I know of no means of judging, *à priori*, as to the eligibility of using wine. This point, as well as that of increasing or diminishing the quantity, can be learned only from the effect—that is, by *experiment*. In a doubtful case, I have always reasoned with myself, that a wine-glassful of claret and water could scarcely do harm, even where marked excitement was present, while its effects would enable me to judge of the susceptibility of the system to its influence, and the expediency of increasing the quantity, or *vice versâ*. Generally speaking, cases with a moist skin bear wine better than those where the skin is parched and dry; and slow and

* For this observation I am indebted to the late Dr. Robert Perceval—a physician without a superior among his contemporaries or successors, whether we consider his professional and scientific attainments, or his acquaintance with elegant literature. Many years since he predicted the revolutions that have since taken place in medicine, and boldly raised his voice against the delusive theories of the day, and the equally delusive theories which were destined for a time to supersede them. He considered no subject, however apparently trivial, as undeserving the researches of his powerful mind, provided it could add even an atom to the mass of useful medical knowledge, or contribute to the welfare or comfort of his fellow-creatures. *Vixit post funera virtus.*

gradual debility at a late period, better than where this occurrence is abrupt and early. To such and all other rules there are, however, numerous exceptions.

It is obvious that a man of luxurious habits, accustomed to the use of wine, must require a much larger quantity of it to produce a given effect than a lady who perhaps did not drink a glass for his bottle. In the average of cases from four to eight ounces of port-wine is the quantity found to be most beneficial at Sir Patrick Dun's hospital. It sometimes happens, however, that in a case of collapse, amounting almost to inanition and apparent extinction of life, the vital powers are preserved, and recovery effected, by the use of a bottle or more of wine daily. Yet where such treatment has proved successful, it has always, as far as I have observed, been the result of a gradual increase of wine up to the quantity fore-said—a feeling of the way—and not by a hap-hazard use of it, which generally fails or proves injurious.

Whether circumstances justify the use of a single glass of wine, or of one or two bottles daily, the same rules may be applied. 1st. If wine is agreeing, and the patient is improving, "let well enough alone." The quantity of wine ought on no account to be increased—nay, if it be already large, it is to be borne in mind that as the patient improves he will become more and more susceptible of its stimulus, and therefore the medical attendant ought to be rather beforehand with the symptoms of excitement, and to diminish the large quantity of wine before they appear. 2dly. If the symptoms indicate that wine is disagreeing, the quantity ought to be reduced, the quality of the stimulus changed, or it ought to be laid aside, according to the degree or duration of such disagreement. 3dly. If wine is producing no effect whatever, and the symptoms of debility are progressive, as before its administration, the quantity ought to be cautiously increased.

When wine is agreeing with a patient in fever, we observe an amendment in the symptoms, which seems to the observer as if it were the spontaneous effort of nature, and not the result of the influence of a stimulus. The patient becomes stronger, more conscious, and less restless; the pulse is slower and firmer, and the tongue cleaner; even the skin, if previously parched, becomes cooler. But there is nothing resembling the stimulating action of wine on a healthy person—no acceleration of the pulse, or flushing of the countenance. Wherever such take place, or where the favourable symptoms consequent on the use of wine just mentioned are observed to be of but temporary

duration, we may rest assured that we are verging on the unfavourable influence of the remedy, and that nothing will be gained, and probably something lost, by continuing to administer it in its present quantity. If the pulse be considerably or permanently quickened, or the patient hot or restless—if there be delirium, headache, oppression, or increased quickness of breathing, or the symptoms of approaching or recurring local inflammation, the morbid influence of wine is obvious.

It sometimes happens that by varying the quality as well as the quantity of the stimulus, it is found to agree, although formerly acting injuriously. Thus white wine will succeed on the failure of red, and *vice versâ*. Malt liquor is sometimes advantageously substituted for wine, and I have seen cases with which the brisk home-made wines agreed extremely well. As a general rule, however, no stimulus is equal to good foreign wine. The cardiac mixture which preceded its use ought to be continued along with it.

The cases which bear porter or ale better than wine are those where, with great exhaustion or emaciation, there is also much excitement, or a tendency to pulmonary irritation. Malt liquor, as being more nutritive and less stimulating, is often preferable in such cases. It is also well adapted, in conjunction with wine, where there are bed sores, erysipelas, or gangrene, conjoined with fever. It is unnecessary to add, that porter or ale ought to be of the purest quality. Sydenham was a great advocate for small beer. In some cases, where great determination to the head or the co-existence of pneumonia, bronchitis, or pulmonary irritation, rendered the use of wine inadmissible as a means of withstanding the advance of collapse, I have allowed the patient a quart or more of light table beer in the course of the day. Thirst was quenched, and the strength preserved by this treatment, till the typhoid disease underwent a favourable change, and this without any aggravation of the pulmonary or cerebral symptoms. The rules for the administration of malt liquor are similar to those for the use of wine, as to the increase, continuance, or diminution. In cases of great debility it is often preferable to administer the large quantity of stimulus that the patient requires in different forms. For instance, instead of allowing a bottle of wine daily, to give half a bottle of wine and a bottle of ale.

Spirituous liquors are liable to the objections applicable to wine, without possessing its advantages—that is, they rather produce temporary excitement than permanent strength. In cases of great de-

bility, however, a spoonful of brandy may be added to the patient's candle, panada, or arrow-root, which is often lighter thus than by the addition of wine. A more active administration of spirituous liquors is only admissible in cases where the patient has been habituated to their excessive use—where wine acts like water, and spirits like wine. Fresh barm is a great favourite with the Dublin physicians. It certainly agrees best with what are called the putrid cases. Two or three spoonfuls may be added to a pint of ale or beer. Some practitioners administer ale-wort, or infusion of malt boiled with hops, during the process of fermentation with yeast. Care is requisite in its preparation. The infusion is to be made by percolating water through the malt. Directions for this purpose are given in Mr. Donovan's treatise on Brewing, in Lardner's Cyclopædia—London, 1837, vol. i. p. 205. The directions must be strictly followed, or the requisite chemical changes will not take place. A quart of wort prepared by means of any small straining apparatus will require about two pounds of ground malt, a quarter of an ounce of hops, and a table-spoonful of barm. The water required will be nearly two quarts; the first half being added nearly, and the second altogether boiling, for the reasons stated by Mr. Donovan. A decoction of malt and hops made in this way, but in larger quantity, and without the addition of yeast, inspissated by heat to the consistency of molasses, is an excellent demulcent during irritation of the bronchæ, from whatever cause. A tea-spoonful is to be taken occasionally.

In cases of great debility, especially if connected with local gangrene, and where other nutriment fails in supporting the strength, the patient may be nourished by means of beef gravy or osmazome, given in spoonfuls from time to time. A pound of very fresh, juicy, and lean beef, will afford about a quarter of a pint. The raw meat is to be sliced, scored on the surface, sprinkled with a little salt, and put into a close vessel with two spoonfuls of water (not more) over a slow fire, for from twenty minutes to half an hour. The juice exudes under the influence of the heat, and is ready for use.

It is an aphorism in fever, that the patient is never to be given up. Cases have repeatedly occurred, where the physicians have taken their leave during what was supposed to be the death-struggle—nay, life has been supposed to be extinct, and the body put into the coffin, and yet the patients are at present alive and well. The favourable turn in the disease, often scarcely perceptible at first, is therefore always a matter of reasonable hope, even

in the apparently worst cases. Every mode is to be had recourse to to prevent the extinction of the vital spark: wine—burned brandy (in such cases)—beef gravy—musk—cardiac mixtures—and counter-stimulus, by means of blisters to the calves of the legs, the upper arms, and the nape of the neck. The sores produced by the last mentioned applications often, however, prove troublesome subsequently, and require careful treatment. When we consider, indeed, the slender link which connects the patient with existence in this world, it must be obvious that the slightest variation in the performance of professional duty must often strike the balance between life and death, and that every the slightest aggravation of the danger ought to be withstood by adequate precautions. During the period of utter helplessness and unconsciousness the patient is exposed to additional peril from three causes: inattention to cleanliness—stripping and sloughing—and retention of urine. To these I shall next direct my observations.

PHYSIOLOGICAL PROBLEM.

BY WILLIAM GRIFFIN, M.D. Limerick.

Does suffering necessarily imply consciousness? Are sentient beings necessarily percipient?

NO. II.

THE term consciousness has been used by metaphysicians in two senses: the first an exceedingly limited one, implying merely the existence of a sensation, thought, or desire—a pure sense in fact of being or of existence; the second, or true and popular sense of the word, “a belief in the existence of the sensations and thoughts which pass through our minds, and of our own existence as the subject of them*.” In the former sense it is simply another term for sensibility, and is used indifferently for it by Brown, who denies its existence as a distinct faculty. He considers consciousness merely as a general term for sensations, thoughts, or desires, and identifies it with all or any of these, inasmuch as it is, to use his own words, “impossible to feel and not to feel at the same time;” by which he means, that it is impossible to feel and not be conscious at the same time. Now this is the very point at issue; for if

* Alison's Physiology, p. 215.

there be a class of pure sentient as distinguished from thinking beings, which we shall shew is more than probable, the one can only possess a sense or feeling of existence or pure sensations, while the other experiences conjointly with these sensations a perception of them, with a belief in their own existence as the subject of both. No general term, therefore, applying to the two definitions indifferently, can be admitted in physiological reasoning without leading into continual error; so discarding the use of the word consciousness in the first sense attached to it, expressed much more simply by sensibility or feeling, we shall employ it only in that full meaning in which it is legitimately and popularly understood.

It will appear that consciousness, in the full sense in which we have defined it, of necessity implies the existence of memory and personal identity. It is difficult to understand how even an intuitive belief in our own existence, as the subject of thoughts and sensations, could exist or occur in any way to the mind, until at least a second sensation or thought was experienced, and remembered as having been experienced, by one and the same being. The mind cannot dwell, even for a moment, in thought or inference on its own existence, without including the existence of memory and individuality, since the occurrence of the thought or inference must have arisen from a previous thought or sensation remembered as having been experienced by the same being. Pure sentient beings, if such exist, may have a sense of existence; and this is all, I believe, the infant has in the first moments of life, or can have until it is capable of perceiving its own perceptions. Mental consciousness, as distinguished from mere sentient consciousness, sensibility, or feeling, therefore implies not only the perception of thoughts and sensations, but the reference of these to something that remembers the experience of a former thought or sensation, which believes it existed before the present moment, and that it was itself which experienced both.

The distinctions here drawn between sensation and consciousness have always been recognized by metaphysicians, though they continually confound or identify them in their application. Brown, who altogether rejects them, is,

indeed, consistent in using the terms indiscriminately, yet he sometimes used the word consciousness in a more extended sense, not simply implying a mere sensation as the consciousness of the moment, but a series of feelings or sensations. "If the mind of man," he says, "and all the changes which take place in it, from the first feeling with which life commenced to the last with which it closes, could be made visible to any other thinking being, a *certain series of feelings alone*, that is to say, a certain number of successive states of the mind, would be distinguishable in it, forming, indeed, a variety of sensations, and thoughts, and passions, as momentary states of the mind, but all of them existing individually and successively to each other." To this whole series he gives the name of consciousness.

Now consciousness, as has been shewn, in its very essence implies individuality, and we can conceive its divisibility as little as we could the divisibility of mind, or the thinking principle; while, if Brown's definition were admitted, and that we could suppose it to consist in a long series of feelings, without any connecting link or subject, and without any necessary or obvious relation to one another, there is no difficulty in conceiving the divisibility of an animal with such an amount of consciousness, each segment retaining the same consciousness as the whole. That consciousness which consists in a mere sense of the present, neither including remembrance of the past nor anticipation of the future, is not of necessity indivisible, or attached to a single existence, as mental consciousness must be; but the consciousness which implies sense and perception of the present, with memory of the past, includes all the individuality which mind comprehends, and to suppose the possibility of its division would be, in fact, to suppose not only the possibility of a single consciousness or mind becoming two minds, and capable of existing in different states at the same moment, but of each mind remembering the past as wholly experienced by itself. Consciousness, therefore, in Brown's exposition of it, is nothing but pure sensation, or what is popularly termed feeling, without thought, or memory, or knowledge, or belief of its own existence; while, in its ordinary and proper acceptation, it implies not only a knowledge or belief of

the existence of the sensations felt, but of the being who experiences them*.

All that can be essential to consciousness, thought, perception, memory, belief, we have already seen, are connected with the cerebral hemispheres, and perish with them; volition, therefore, as far as it is understood to be a purely mental act, must also be considered as strictly dependent on the same organs. Like consciousness, it has been used very vaguely, some applying it to all actions of the muscles which are under the control of the will; others limiting it to those actions in which there exists the consciousness of a mental effort. The latter limitation is obviously founded on a strict sense of the popular understanding of the term, as well as its essential relation with those faculties which exist in connexion with the cerebral lobes. The actions which take place after the destruction of those lobes, and in connexion with another part of the nervous system—the spinal cord—however they may evince proofs of design in the adaptation of means to ends, can be looked upon as instinctive or sentient only (if, indeed, the instinctive and sentient functions survive the destruction of the brain); and before even any reasoning can be admitted in support of an opposite conjecture, it must be experimentally demonstrated that the faculties essential to consciousness, and therefore to volition, have no necessary dependence on the brain; which I do not believe can be done.

We have, indeed, abundant proofs, both analogical and direct, that the cerebral lobes are essential to the existence

of consciousness; and yet, since all the phenomena usually considered indicative of it—motions expressive of volition, of suffering, of design, and even spontaneous actions—appear to survive the destruction of those lobes, it follows at the least, from all we have stated, that our sole means of determining whether certain muscular movements are the result of consciousness and volition, or of an independent sentient faculty, must rest in the definitions which we attach to the words, and in the anatomical relations of such faculties as are essential to the fulfilment of those definitions. This is, indeed, the only true mode of arriving at just notions of the physiology of the brain, or of the mental functions; and it is because it has never been adopted by psychologists that the received doctrine of mind cannot by possibility be reconciled with the new facts daily arising from the rapid improvements in physiology. "All that we know of the body," says Reid, "is owing to anatomical dissection and observation; and it must be by an anatomy of the mind that we can discover its powers and principles," as if those powers or principles, studied without reference to the organs with which they are connected in life, could be correctly or with certainty distinguished and understood, any more than the functions of assimilation without reference to the organs concerned in them. To assume the examination of mind distinct from body, is to examine the operation of our own minds distinct from the conditions under which only we can be conscious of them: it is as if we attempted to attain a knowledge of the visual power by studying our perceptions of objects, without reference to the organs which alone can furnish the conditions under which vision takes place. The liability to error in inquiries so conducted is well illustrated by the difficulties in which the philosophy of mind has been involved by modern discoveries, which seem to have almost demonstrated that thought and feeling reside not only in different, but in distant parts of the nervous system, and that the latter may exist independently of the former. This will appear still more clearly in some experiments which, returning to our inquiry regarding the organs concerned in consciousness and volition, we shall now instance. It will be seen that they place metaphysicians on either horn of

* It is singular that Brown, while denying the distinctions here insisted on, points to them incidentally in his reasonings on various occasions. It would be difficult to draw a clearer picture of a *sentient being*, as compared with a *perceptible one*, than we find in the following extract:—"Even if by some provision of nature our bodily constitution had been so framed as to require no subsistence, or if instinctively and without reflection we had been led, on the first impulse of appetite, to repair our daily waste, and to shelter ourselves from the various causes of injury to which we are exposed, though our animal life might have been extended to as long a period as at present, still, if but a succession of momentary sensations, it would have been one of the lowest forms of mere animal life. It is only as capable of looking before and behind—that is to say, as capable of those spontaneous suggestions of thought which constitute *remembrance and foresight*—that we rise to the dignity of intellectual beings." In common with other metaphysicians, Brown also frequently uses the terms *sentient mind* and *perceptible mind*, as if he meant two essentially distinct and independent faculties.

a dilemma, leaving them to declare that consciousness admits of division, and of existing as so many new and perfect consciousnesses or minds as there are divisions, or that all the phenomena which have been hitherto considered essentially dependent on, and characteristic of, consciousness, may exist without it.

No one, with the notions of consciousness and sensation at present universally received, will deny their possession to an earthworm: its sensibility to irritants—the voluntary nature of its movements—the freedom with which it appears to choose its means of escaping from danger—the certainty that it hungers and thirsts and has sexual appetites, all seem corroborative of the fact. From the simplicity of its organization, too, and the extent to which it admits of being divided into segments, each segment still retaining the conditions essential to its organization, it appeared to present the fairest subject for experiments regarding consciousness that could be selected. These experiments were found to furnish the following results:—

An earth-worm was suddenly divided into nearly equal parts. The anterior part moved rapidly away without much apparent suffering; the posterior writhed itself violently as if in great pain; but after a few movements lay quiet. It continued so for about a minute, and then moved on with the wounded end foremost, progressing at first slowly, but afterwards quite as actively as the anterior part. It sometimes selected a course to the right, sometimes to the left, without any obvious cause. Occasionally it rested, remaining quite motionless, so that I thought it would not move again. In some short time, however, and without the application of any stimulus, it moved onward spontaneously again. There was, indeed, no possibility of distinguishing it from the anterior part except one looked sufficiently close to detect the wounded termination of the former, so different from the pointed head of the latter. At one time, when progressing steadily on, it was observed to stop suddenly to evacuate, as a cart horse does on a journey, and after very deliberately discharging the contents of the bowels it moved on again.

Another earth-worm was divided also in the middle; the fore part moved

rapidly away; the tail part writhed as before, then remained quiet for half a minute or more; after which, without the application of any irritant, it moved on like the anterior part. When it came in contact with a pin stuck perpendicularly in its way it moved to one side; when two pins were stuck before it so close as scarcely to allow room for passing, it got apparently jammed between them, after which it shewed no disposition to move until stimulated.

When the same experiment was tried with the tail part of another earthworm, allowing more room between the pins, it first came directly against one of the pins, then turned a little and began to pass it; but immediately after, as if changing its mind, drew back and passed forward between the two pins. When a penknife was placed crossways in its path it first stopped, then turned its wounded part to the right and moved along the surface of the knife in a direction at a right angle with its former course.

Another earth-worm, nearly three inches in length, was divided with a sharp scissors about three quarters of an inch from the head. The anterior part, instead of running rapidly off, as in the former cases, contracted itself suddenly and lay still, while the posterior darted away tail foremost across the table, as if in excessive alarm. When it had traversed a good distance, fearing it would fall off the table, to the edge of which it was approaching, it was touched at the tail (the foremost point as it progressed) with a probe, upon which it instantly reversed its movements, taking a directly opposite direction without turning, the wounded part being foremost. The anterior part of the worm all this while lay very quiet, but it now began to lift its nose and snuff about, turning its pointed head now to the right, now to the left, yet still retaining its place, so that I began to think it was either glued to the table by the moisture, or had lost the parts of its body necessary to progression. On putting a little bit of earth near it, it coiled round it, and remained so. The posterior part of the worm was meantime continuing its exertions, when suddenly, and without any external cause that I could possibly divine, the anterior piece set out on its travels. As it happened to take the direction of the posterior piece, it seemed almost as if it was going

in search of it. The posterior part had by this time got to the edge of the table, upon which I watched its movements with great curiosity. It first stretched its foremost or wounded part out beyond the table, to look for support or something to cling to; but not finding any thing within reach it turned it in, and fixing it to the perpendicular end of the table, about half an inch or more from the upper flat surface, it arched its body as a leach would until the tail nearly reached the margin of the table, when losing its hold, it fell to the ground. On being taken up it was still lively and inclined to move, but I took no further notice of it.

Another earth-worm was divided into three parts; about half of it having been left to the centre portion, and a fourth each to the head and tail. The two latter writhed a good deal after the division, and then moved on slowly and feebly. The centre piece moved on more actively, changing its direction to right or left, and avoiding obstacles as the former segments did*.

Satisfactory as the experiments on the higher or more perfect animals must be deemed, in proving the persistence of the phenomena which are considered indicative of consciousness after the removal of the brain, they were still open to objections on the part of those who consider the results as wholly opposed to the old and acknowledged doctrines. But here is an animal, the earth-worm, to whom consciousness is fully conceded, and to whom, if it was not conceded, it would be idle to argue on the subject, since no other principle could be shewn, by those who identify consciousness and sensation, as capable of producing the same phenomena; here, we say, is an animal, each segment of which, after division, enjoys the same apparent consciousness and volition as the entire, highly sensible, moving about freely, as feeling or caprice prompts it;

* In several such experiments I found that when the worm was divided into three portions, the motions of each are more languid and feeble than when divided into two; and when divided into two unequal ones it is feeblest in the shortest piece, whether it be the anterior or posterior. When divided in the middle, the anterior part is always at first the more active of the two, and usually moves on without much appearance of pain, while the posterior one writhes and seems to suffer, though it eventually moves on also. When the posterior part is the longest it sometimes hurries off without any convulsion or writhing, the suffering in such case appearing only in the smaller segment left behind.

resting when tired, travelling on when rested, avoiding obstacle, endeavouring to overcome difficulties, and all spontaneously. It may be fairly inquired, how will this be accounted for by the metaphysician? It will not answer to say, as has frequently been said, that in the lower orders of animals (as the invertebrata) the sensorial property becomes less and less concentrated in single masses, and the character of individuality ceases to attach to the sensorial phenomena. As a statement of a fact it may be undeniable, but if intended as an explanation it must be regarded as absurd mystification on the part of those who cannot conceive the existence of any degree of sensation without consciousness. If such animals enjoy sensation at all in any shape or degree, they enjoy consciousness according to the received doctrines, and consciousness, even in the lowest degree which the metaphysician attaches to it, includes individuality as much as it does in man. Consciousness is, in fact, the thinking principle attending to its own acts*, and can be conceived no more divisible as such, into two perfect and independent consciousnesses in the lowest than in the most perfect organization.

How then are we to regard these extraordinary phenomena? how are we to explain these facts, of animals exhibiting all the indications of consciousness and volition, yet surviving the destruction of the organs on which true consciousness is dependent? If we again revert to the experiments which raised this difficulty, and endeavour to ascertain whether they can suggest any clue that may lead us out of it, we find that with the removal of the brain, all the strictly mental faculties which animals possess—memory, perception, and the association of thoughts, wholly disappear; while life and all the usual indications of sensation, and all the instinctive acts most closely linked with sensation, remain. The creature swallows what is put into its mouth, moves its legs when irritated, and its wings when thrown into the air; but, when not excited by any impression made on the senses, appears in a state of stupor or profound sleep, gives no signs of recollection, even of sensations just felt, nor

* "Consciousness appears to mean simply the act of attending to what is passing in the mind."
—Abercrombie.

of such emotions as sensations were wont to excite; and cannot seek its food, nor even avoid obstacles thrown in its way.

If we were not prepossessed with invincible notions of the identity of sensation with the thinking principle, or of its being simply a condition of mind, it would at once occur to us from these facts, that there was an essential difference between sensation and perception—between feeling and consciousness; and that although it might be, that every thing present to the senses, or felt, must also be perceived by all animals having a percipient organ or brain, it does not follow that such animals as are deprived of it, or who never were possessed of one, should not feel. It would, I think, occur to us, that there may be large classes of purely sentient animals as there are of percipient ones, and that in the diseases or accidents to which even the highest organizations are subject, the independent existence of both descriptions of being is illustrated. In apoplexy, in epilepsy, and in profound sleep, in the acephalous fœtus, and in decapitated animals, we have a tolerably perfect illustration of pure sentient existence; and if it be thought so difficult to conceive sensation without perception or consciousness, that we are fain to admit the presence of the latter in those cases, it should be recollected that it is still harder to conceive the presence of perception without a percipient organ, which we have the strongest grounds for believing the brain to be, or the divisibility of consciousness, such as appears to take place on dividing an earthworm or a polypus into segments.

The difficulty one at first feels in conceiving sensation distinct from perception arises from the fact just stated, that sensation is almost always necessarily perceived in percipient beings, and when not perceived is not noted or remembered by the mind, and so cannot become a subject for observation or argument. Sensation and perception seem thus to be co-existent, and become in some sort identified. It is a singular fact, however, that invariably as this identity is assumed alike by the uninformed and the philosopher, both acknowledge distinctions and frequently apply these terms differently, and in senses that would not admit of their being exchanged for one another. There

is, indeed, no work treating of the mental faculties in which we do not meet with distinct definitions of sensation, perception, and consciousness, and long chapters specially devoted to each, although we are afterwards, in their application, certain to find the identity, of at least the two former assumed.

Dr. Brown defines sensation to be the simple impression made upon the organs of sense; perception, an association formed between this impression and an external substance, which we have ascertained to be concerned in producing it. Dr. Abercrombie describes sensation as implying the corporeal part, and perception the mental part, of the process by which we acquire a knowledge of external things. Reid applies the term sensation to the changes in a part of the nervous system, called the sensorium, consequent on an impression made on an organ of sense, by something external to it; and the word perception he applies to the knowledge of the presence and the qualities of that something following the sensation. "The impression," he says, "made upon the organ, nerves, and brain, is followed by a sensation, and last of all this sensation is followed by the perception of the object."

The distinction will be understood more readily by the simple illustration given by Mr. Mayo. "I look," he says, "at an object of such dimensions that a single glance serves to satisfy me of its nature: the impressions which I receive through this experiment are three-fold:—1st, a present sensation of colour; 2d, a conviction that the sensation is excited by something external; 3d, a notion of the true size, and form, and distance of the object, which I have seen. The first of these impressions constitutes pure sensation; the second, or the notion which we form of something external as the cause of sensation, constitutes perception; the third class, of impressions described, and which we have learned to associate with the preceding, are our required perceptions."

What we give the name of perception to in common it is true is always made up of impressions, sensations, and perceptions, the latter including the two former; but when we come to examine and define them more particularly, as we have here done, it does not appear that the existence of the former so necessarily includes the latter. If, indeed,

there be any difference at all inferred in the definitions given, it must be admitted that every successive action in the series forming perfect perception may exist, though not followed by that which should naturally succeed it: thus the first impression on the nerves or brain may take place without being followed by that change in the sensorium called sensation, as when a limb which has lost its sensation is irritated, or an amaurotic eye exposed to the light. Again, sensation may take place without being succeeded by perception, as we have reason to believe occurs in apoplexies—in the acephalous fetus, and perhaps in new-born infants—in decapitated animals, and in the segments of those animals which admit of division, without destruction of the organization essential to the life of each segment. Lastly, such instinctive perception may take place without the acquired, of the truth of which we have no need of illustration.

[To be continued.]

CASE OF PUERPERAL MANIA, WITH REMARKS.

To the Editor of the Medical Gazette.

SIR,

IN your report of the proceedings of the Physical Society, Gny's Hospital (Gaz. Nov. 12, 1838) is an account of a paper by Dr. Ashwell, and discussion on the morbid effects of undue lactation, with remarks on puerperal mania. If you should consider the accompanying case of this latter disease, which has lately come under my notice, worthy of recording, I shall feel much obliged by its insertion in your journal, with some few observations connected with it.

Your obedient servant,

J. D. JEFFERY,
Surgeon, &c.

Sidmouth, March 10, 1839.

On Monday, Dec. 12, I was sent for to see Mrs. Slade, who had engaged me to attend in her confinement, expected to take place about Christmas. She is a thin spare woman, with pale countenance and large dark eyes; has had four children. She fancied the pains of labour were coming on, and evinced great anxiety of manner. I found from

conversation that the pain she had felt was exceedingly slight, and occurring at long intervals.

Ordered an opiate, and desired her to go to bed early.

13th.—Found her in her room; her manner was strange and incoherent; she wished me to make an examination. I found the head of the child low down; os uteri dilated about the size of a shilling, but rigid, and strongly contracting on the finger; pulse 90, soft. Ordered—

R Mist. Camphoræ, ʒrss.; Tr. Opii, ʒiiss.; Sp. Lavand. ʒj. M. st. coch. dua magna 6ta quaque horâ.

In the evening I found her exhibiting all the symptoms of puerperal mania, rolling about in the bed, exclaiming loudly, and saying the strangest things,—among others, that her husband, who was then absent, had been killed. Pulse still 90, and soft; and her bowels not having acted since yesterday, ordered—

Ol. Ricini, ʒiss.

14th.—Has passed a very restless night, with seeming symptoms of labour pains. She stares vacantly at every one around, and utters various exclamations; now grasping at vacancy, then apparently endeavouring to stifle herself in the bed-clothes. Perspiration covers the body; os uteri not more dilated than yesterday; pulse still soft, and not quicker. Bowels not having been opened, ordered—

Three strong aperient pills, continuing the mixture twice a day.

15th.—Has passed a very troublesome night, being with difficulty kept in bed; bowels have not acted. She now refuses to take any thing, except occasionally a little wine and gruel; she refuses medicine, exclaiming, "it is poison." On making an examination I find the os uteri *in statu quo*; and on endeavouring to dilate it, it contracts and pinches the fingers; it is turned very much towards the sacrum, and tilted upwards. Pulse about the same as before.

Ordered an enema.

16th.—Has passed a quieter night, but still looks wild, and is insensible; takes more nourishment than yesterday.

Ordered a dose of strong aperient medicine.

Evening. — The medicine has produced several copious evacuations, since which she has been much quieter, and answers many questions rationally. The os uteri is not so rigid, and is somewhat more dilated. I then thought it advisable, in concurrence with the opinion of my fellow-practitioner, Mr. Hodge, who then accompanied me, to endeavour to bring on labour. Ordered—

℞ Tr. Secale Cornut. ʒvj.; Tr. Cardam. C. ʒij.; Aquæ, q. s. ut ft. mist. ʒvj. st. coch. dua magna omni horâ.

17th.—I was called in a great hurry this morning, at half-past eight. I found her lying on her back, looking wild and pale, and talking incessantly. On making an examination I found the head of the child without the vagina, and she had it grasped firmly in her hand. A pain soon came on, and delivery was accomplished. She seems quite unconscious of what has taken place. The placenta soon followed, and no hæmorrhage occurred. Her attendants informed me that she had slept four hours in the night, and had taken six doses of the medicine. The pulse after delivery was 80, and she had taken a glass of wine and water.

2 o'clock, P.M. — I find her still talking incessantly; pulse has risen to 100, but soft and weak. Ordered—

Sixty drops of laudanum, to be given in water as an enema; and

℞ Mist. Camphor. ʒiv.; Liq. Opii Sedativ. ℥xxx. M. st. 4am partem 4ta quâque horâ.

18th. — Has passed a very restless night; her attendants could scarcely keep her in bed.

Ordered an aperient enema and draught, the bowels not having been opened for twenty-four hours.

Pulse reduced to 80; her feet being cold, mustard cataplasms were applied, which remained on an hour.

19th.—Still the same in most respects, but the pulse is lower—70; bowels have been copiously relieved during the night; evacuations not unhealthy. She takes beef-tea, and occasionally wine and gruel. I now gave her the Ol. Terabinthine in drachm doses, with Mucil. Acaciæ, and Mist. Camphor. every four hours.

12 P.M. — Her raving is worse. I found her with the straight-waiscoat on. Has taken two doses of the medicine,

which has not affected the bowels. Ordered the region of the cerebellum to be shaved, and a blister applied.

Ordered a mixture containing Antimon.

Tart. gr. iv. st. 4am part. quartâ quâque horâ.

Narcotics seeming to do rather harm than good, it occurred to me that the hydrocyanic acid—as a medicine which may be called purely sedative—might be the best adapted to her case.

℞ Acid. Hydrocyanic, ℥v. Mucil. Acaciæ, ʒij. Aquæ, ʒj. ft. haust. quartâ quâque horâ sumend.

22d.—She has passed a better night, and the nurses say she became more tranquil soon after taking the first dose of the medicine. I find her more sensible.

Evening.—Still better, and has been quiet through the day.

Continue the medicine.

23d.—Has passed a tolerable quiet night, and is certainly slightly improved since yesterday. The nurse says she is decidedly better after each dose of the medicine, which I ordered to be continued.

24th.—She continues to improve rapidly. Having taken twelve doses of the acid, I deemed it unnecessary to proceed with it further.

February 19th.—She has been on a visit to some relations, and is returned perfectly sensible, and to all appearances well.

REMARKS.—Puerperal mania is not a common disease, and therefore it is not every one, perhaps, of your readers who will take the same interest in the report of this case: but there are circumstances connected both with its appearance and the treatment, which, I trust, will not be uninteresting to some.

1st. It is not usual for mania to come on before delivery; it commenced in this case at least five days previously. All writers on the diseases of women, and Dr. Gooch in particular, treat of puerperal mania; but I find none, as far as I have the means of ascertaining, who mention it but as a consequence of childbirth.

This disease is fearful under any circumstances; but it becomes much more so to the medical attendant in particular, when he has to contemplate the difficulties and chances of delivery in a patient who is insensible, and whose violence

often prevents the possibility of even an examination.

As soon as I could be certain that the os uteri was sufficiently dilated, and without much rigidity, I deemed it advisable, in conjunction with the opinion of my fellow-practitioner, to endeavour to hasten the process of parturition; hoping that when the uterus was relieved of its burden, the sympathetic effects on the nervous system would be abated, if not cease. And here is to me the second point of interest—viz. that I am furnished with another in addition to the many proofs I have before had of the power of the *secale cornutum* to effect, under certain circumstances, a safe and effectual action of the uterus. Delivery was accomplished safely and easily in a reasonable time, and, I believe, hæmorrhage prevented, which would, in all probability, in this case have been ultimately if not immediately fatal.

3dly. The cerebral affection exhibited in the form of mania, the peculiarities under which they were excited, and the effects of different remedies, afford matter for contemplation.

The patient had been subjected to much mental anxiety, as well as bodily exertion, previous to her illness; having for some time performed the office of carrier, and driven a waggon to Exeter, a distance of sixteen miles, for her husband, who neglected his business, and also ill treated her, which doubtless induced that depression of the corporeal powers and excitement of the nervous system which led to her ultimate attack.

With regard to remedies, I certainly am of opinion that the hydrocyanic acid was productive of the greatest benefit.

I am aware that the remedy last used is apt to receive the whole, and often very unmerited praise; but in this case I did not depend on my own observation. I was much gratified on questioning the nurse, who, of her own accord, dated the improvement and tranquillity of the patient from the first exhibition of the medicine, and moreover stated, that “she became quieter after each subsequent dose.”

From the results of the above case, I should be induced to try, in a similar one, the hydrocyanic acid in preference to other medicines—such as opium, hyoscyamus, &c. which may be called narcotico-sedative.

The hydrocyanic acid seems to act

purely on the nerves themselves, without deranging the circulation to produce narcotism; and thus I am led to believe that it is a remedy very superior to most other medicines, inasmuch as its effects are purely sedative.

In that peculiar lancinating pain felt at the epigastrium, like dyspeptics, I have often found the hydrocyanic acid act like a charm: but it must be administered in a simple form—such as with gum arabic and water. I believe its efficacy is much diminished by an admixture with other drugs, particularly with those of a stimulating nature.

After my experience of its action in the above case, I was led to think that prussic acid would be a useful remedy in delirium tremens; and at my request it was tried by my friend, Mr. Hodge, on a patient of his who was labouring under that disease in its worst form. He informs me that his patient, under its exhibition, became much quieter, but the case being an extreme one, and the man ultimately dying, I do not adduce it as a proof of the correctness of my views.

But, nevertheless, I think there are no two diseases which exhibit symptoms so nearly alike as delirium tremens and puerperal mania; and I believe there are no two organs in the body whose sympathies with the brain are more intimate and sensitive than are the stomach and uterus. A thought, we know, or sudden unpleasant intelligence, will disorder the functions of digestion; and again, indigestible matter or stimulating fluids in the stomach will occasion violent disorders of the mind, and often fatal effects on the brain. On the other hand, how intimately is the excitability of the uterus, considered as a sexual organ, connected with the thoughts and imaginations of the mind; and during gestation, in particular, most of its disorders are referable to the mind. With this knowledge, then, we cannot be more surprised that mania should occur through uterine sympathies, than that delirium tremens should be the result of a constant repetition of spirituous stimuli in the stomach.

With these views, I would venture to suggest to the profession a trial of the hydrocyanic acid in some cases of extreme nervous affections, but more particularly of delirium tremens, which too often prove fatal, or are painfully protracted, through the failure of remedies in exerting any control over them.

MEDICAL GAZETTE.

"Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri: potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

USE AND ABUSE OF PURGATIVE MEDICINES.

THE trite and just observation that nations are benefited as much by the interchange of ideas and mutual criticism, as by the barter of commodities, is verified by every day's experience. The dullest traveller comes back convinced that "there be livers out of England," (at Strasburgh, and elsewhere); and the toleration which he has been forced to learn for habits and feelings the most alien to his own, he extends to the less marked deviations of his own countrymen. Every improvement, too, flies on the wings of steam and newspapers, from North Cape to the Ganges; and, as far as social progress is concerned, the *grande pensée* of Henri IV. seems about to be realized, and Europe to become fused into one vast empire.

In medicine, the advantage of this mental traffic is equally conspicuous. The practice of a judicious physician is at all times eclectic; he is a sworn partisan neither of Boerhaave, nor Cullen, nor Broussais; and though many sound practitioners still call themselves followers of Hippocrates, this is only because they have found that Hippocrates is another word for nature. Yet it must be confessed, that in spite of this constant approximation of opinions, there is a strange dissension, on many points, between the best physicians of neighbouring countries, and on no topic more than the one which we have selected for the title of this article. But even here the distance, though great, is smaller than before; the practitioners

of France are less exclusively devoted to enemata, and those of England less Hamiltonian, than they were some years ago. The doctrines of Broussais, though pushed to a preposterous extent, have directed the attention of the whole medical world to the effects of drastic purgatives on the inflamed mucous membrane of the stomach and bowels; while, on the other hand, French practitioners, sore afraid and trembling at the experiment, have tried the effects of brisk purgatives, and marvelled to find the patient not only alive, but better.

In this country, although the reaction against the Hamiltonian system began long since, it has probably not yet reached the true medium; and we are therefore not sorry to see that so able a man as Dr. Holland has added his testimony in favour of milder measures, and occupies the middle point between the French physiologist and the Edinburgh physician*.

The first objection made by Dr. Holland is to "the system of giving daily purgatives, and insisting upon daily evacuation; making this the habitual management in health, and treatment in disease."

He observes, that the constitution of different persons varies on this point, and that it is generally absurd, therefore, to endeavour by medicine to force different systems into an unnatural uniformity. This is true; but we think that he has not allowed weight enough to the circumstance, that, although some healthy persons are exceptions, yet the general rule is, that an evacuation takes place daily—a rule with which Locke seems to have been thoroughly impressed, as he wishes children to be *taught* to have a stool every morning. It would, however, be assuredly a great improvement in practice, if the physi-

* Medical Notes and Reflections. By Henry Holland, M.D. F.R.S. &c. Chap. viii. *On the Abuse of Purgative Medicines.*

tian were to ascertain in every case what was the patient's habit in his best health, and thus avoided the risk of error.

He remarks, likewise, that as sudden and violent diarrhœa frequently produces syncope, and sometimes even destroys the patient; so the tendency is the same, though the effects are less rapid and obvious, where a constant irritation is kept up by purgative medicines. Palpitation, too, whether functional or organic, is often increased by continued aperients, and, in nervous or dyspeptic constitutions, is sometimes originally caused by it; yet this is a nice point of practice, as this irregular beating of the heart may arise from congestion in the liver or other chylopoietic viscera, and require evacuation by stool for its relief.

Dr. Holland has sometimes cured patients who are morbidly anxious for a daily evacuation, by expressly advising that it should take place only every other day, and thus, as Darwin would say, breaking the diseased catenation of ideas in their minds, as well as of actions in their bowels. We rather think that these difficulties arise chiefly where good living and sedentary habits meet in the same person, and that the true cure would consist either in subtracting from his food, or adding to his walking, riding, driving, and rowing; but until physicians become despots, and can compel sick aldermen and other crapulous beings to live on a shilling a day, and work for it, we fear that such cases will remain the *opprobrium medicorum*, or rather *ægrorum*.

On the other hand, Dr. Holland adheres to the doctrines of the purely British school in cases where the head is the part affected, or the system of the vena portæ, or in dropsical effusion depending on disease of the organs connected with that system, or where the

blood itself is distempered. The last case is distinguished by the discharge of dark grumous matter, generally supposed to be bile, but in fact secreted by the intestines from the morbid blood which reaches them. One large dose, moreover, is better, he says, than a repetition of small ones, which is probably true in most instances; though in delicate habits it may be necessary for the practitioner to feel his way, and see what fifteen grains of jalap will do, before he ventures on half a drachm.

In fevers, Dr. Holland thinks purgatives should be preceded in almost every instance by emetics, and there ought not to be daily purging. Gastric fever he has found to be the form most benefited by the full use of purgatives—a stubborn fact, enough to make a Broussaist shut up the book.

Though the use of active purgatives is to be confined, as a general rule, to actual disease, yet, like other rules, this has its exceptions; and where there is a strong tendency to accumulations in the vascular system, and to deposits in the cavities, full purging at fixed intervals may be an excellent preventive.

Lastly, he thinks that the combination of tonics with aperients might well be brought into more general use; and has known many instances where calomel, colocynth, and gamboge, were of little avail, while a few drachms of infusion of senna, with decoction of bark, effected all that was desired.

Such are the chief points touching purgatives set forth by Dr. Holland; they will be useful to practitioners, and even more so to unprofessional persons, should the work happen to fall into their hands; as the simple layman is too apt to think that his alimentary tube is a sort of India-rubber bag, which he may clean out as roughly as he pleases—forgetting the good old saw, that a man's stomach is in some sort like his

shirt—the oftener it is washed the sooner it will wear out!

There are some few questions relating to the use of purgatives, to which it would not be easy to find satisfactory answers in the common books, but which are yet most deserving of solution. It may seem strange that any thing should remain to be known concerning rhubarb or castor oil; but those best acquainted with the history of our art will be the first to acknowledge how silent or how bare of evidence it is on many points where we should expect to find countless documents. It is asserted, for instance, that while the impression of most medicines is weakened by repetition, a less dose of castor oil will suffice. This would be curious, if true; but a Louis is wanted to count and register. The disgust that most of our countrymen have to oily medicines is a check to their use, nor do we know that even all the methods recommended by Dr. A. T. Thomson will make it savoury. He says it may be taken “either floating on a little water, and covered with a small quantity of any ardent spirit, or diffused in a cup of coffee; or in cinnamon or mint water, or camphor mixture, by means of mucilage of acacia gum, or the yolk of egg.”—(Dispensatory, 9th edition, p. 624.) He adds, that to make it remain on the stomach some aromatic tincture is generally requisite.

The French, however, as we once before observed, do all they can to gild the pill of life, and make even medicine agreeable; and Magendie prescribes castor oil mixed with an equal quantity of syrup of lemon juice. Whether this attempt is a successful one, we know not.

Is the author of the Dispensatory that we have just quoted correct, in asserting that rhubarb and a neutral salt mutually quicken each other's action, so that a small portion of each taken

together will operate with greater certainty and rapidity than a large portion of either separately? Does that singular combination of a purgative and astringent in rhubarb, which adapts it so well for the cure of diarrhœa, limit its efficacy in other diseases? Does the astringent principle remain behind, after the aperient one has been carried off? or is the subsequent effect dynamic rather than material? It would be instructive, too, if the registers of popular medicine could be unrolled, and we could learn how amateurs administer the more powerful drastics—how they tread on the debatable ground between medication and poisoning. In some cases, no doubt, the limits are overpassed, and the unhappy rustic falls a victim to an old herbal, while in others he is saved, contrary to all rule, by the toughness of his alimentary canal:—

O dura messorum ilia!

CLINICAL LECTURE,

BY SAMUEL COOPER,

Senior Surg. to University College Hospital, &c.

GENTLEMEN,—If it were possible to doubt the advantages of abstaining from mercury in some stages and forms of syphilis, and of relying upon other remedies, I should say that the results of the practice followed by me in this hospital, for the cure of that disease, would be amply sufficient to dispel all such doubt from every mind capable of deriving instruction from experience. Putting out of present consideration the question of the expediency and prudence of being altogether a mercurialist or a non mercurialist, and without attempting to demonstrate the error of clinging invariably to one method or another, I may remark, that what is seen in the wards of this hospital furnishes the most satisfactory proof, that the generality of syphilitic forms of disease, both primary and secondary, do not absolutely require the employment of mercury for their cure. But where the progress of any case towards recovery is slow, or the disease remains stationary, notwithstanding the administration of other remedies than mercury, and there is nothing in the state

of the constitution forming a prohibition to the exhibition of the latter, I recommend you, gentlemen, to imitate me, and let your patients make a fair trial of it.

CASE I.—*Primary Sore and Bubo.*

I have at the present time in the hospital a young man, named Ward, who was admitted, with a well-marked chancre and bubo, about five weeks ago. You know that the primary sore has been healed some time, and that the bubo, which plainly contained purulent matter, is daily subsiding, and the case advancing fast to a cure, though no mercury whatever has been prescribed. Three grains of the hydriodate of potash, with decoction of sarsaparilla, have been given thrice a-day; the chancre has been treated with simple dressings, and the bubo at first leeches and covered with linen wet with cold evaporating lotions; but latterly we have been blackening the skin over it with the nitrate of silver, and now simply applying the hydriodate of potash ointment to the integuments, without friction. This is only one instance out of a great number of a similar kind which have been witnessed here.

The question still remains, will this young man have secondary symptoms? To this I should answer, perhaps he may have them, but possibly the chance of their occurrence will not be materially greater than if he had been treated with mercury; and, as a counterbalance to this, I may remark, that the voice of experience is continually proclaiming the important truth, that when secondary symptoms do follow the strictly non-mercurial treatment, they are of a milder nature than those which often take place after the employment of mercury. Thus, unless mercury be given, we rarely or never see the phagedenic forms of secondary syphilis ensue; and my experience teaches me—as it has taught many others—that, under the non-mercurial treatment, the osseous system seldom or never becomes the seat of necrosis and caries,—and the nose, palate, larynx, and cranium, are not endangered. If these be facts, they must fully justify the kind of treatment pursued in this and some other places, and they will even appear to overrule the abstract question about the comparatively greater frequency of secondary symptoms; for if these are of a milder nature after the non-mercurial treatment, this is, beyond a doubt, a much greater advantage than the other.

Then, gentlemen, we are to remember that our non-mercurial treatment embraces the administration of a remedy, the hydriodate of potash, which would appear to possess considerable power both to prevent and cure secondary symptoms.

CASE II.—*Sloughing Chancre, with profuse Hæmorrhage and Phimosis.*

Charles Rawlins, æt. 21, admitted Feb. 26, 1839. Has generally enjoyed good health, and is not addicted to drinking. About three weeks before his admission, he first observed a sore upon the glans penis. The black wash and some aperient medicines were had recourse to, by which he fancied himself cured. In a few days, however, phimosis came on, and since this occurrence he has not been able to retract the prepuce. On the very night prior to his entrance into the hospital, profuse bleeding took place, which, after the loss of not less than three quarts of blood (according to his own calculation), was stopped by means of cold applications.

On his admission, the penis was much swollen, the skin tense and shining, and of a reddish colour. On the dorsum there was a dark spot, about as large as a shilling: this had made its appearance about eight hours before he came into the hospital. In consequence of the phimosis, and the lodgment of a coagulum of blood within the prepuce, much difficulty was experienced in making water. There was a swelling in each groin—not, I presume, a true bubo from absorption of venereal matter, but in all probability a glandular swelling from irritation in the course of the absorbents. The man's countenance was pale and sallow, and he was so weakened by loss of blood, that he could hardly stand. Pulse feeble and quick.

I ordered a good number of punctures to be made in the swollen and œdematous prepuce, so that the fluid distending its cellular tissue might be discharged. Fomentations were also to be employed, and the bowels cleared out with the calomel and colocynth pills, followed up by the senna mixture and 30 drops of the solution. morph. mur. every night and morning.

Feb. 27th.—The punctures afforded considerable relief, but the sloughing has extended, and on the dorsum of the penis there is now a greyish dark-coloured slough, of about the size of half-a-crown; and in the evening it had become both larger and deeper, penetrating, indeed, at one point entirely through the prepuce.

An incision was made through the prepuce on one side of the slough, and the phimosis obviated. As soon as the glans had been exposed, a large ulcer of a greyish colour was seen, which had already extended deeply into the glans and corona glandis, so as to expose a portion of the corpora cavernosa. The sore was now dressed with the liq. sodæ chlorid.

28th.—The slough is loosening. Poul-tice applied.

March 2d.—The red wash (consisting of two or three grains of sulphate of zinc,

to an ounce of water, and coloured with a little spirit of lavender) now substituted for the poultice. Sore looks cleaner, and granulations beginning to form.

5th.—Sore has now a healthy appearance. Although the chance of the occurrence of secondary symptoms is well known to be materially less after sloughing primary venereal sores than others, I deemed it right (as a further protection to him) to prescribe small doses of the hydriodate of potash (gr. iij.) to be taken thrice a day in $\frac{5}{8}$ ij. of the decoct. sarsæ.

The cure is proceeding quickly, and the swellings in the groin have entirely subsided. The countenance has lost its sallow appearance; the man is recovering his flesh and strength; and the sore, which is only about one-third of its original size, presents a healthy appearance.

CASE III.—*Secondary Syphilis, Ulcers, and Rupia.*

Mary Ford, æt. 34, was admitted December 10, with two considerable ulcers on the arm, and others on the scalp, attended with an eruption presenting very prominent scabs, and the common appearances of venereal rupia.

According to the woman's own history of herself, she had primary venereal complaints eight or nine years ago. She came to us from the St. Pancras Infirmary in a remarkably weak, miserable, and reduced condition, passing restless nights, suffering severe pain in the ulcers, bones, and joints, and with little or no appetite. This, then, was not a case for the exhibition of mercury, unless it had been the aim to convert the sores into rapidly spreading phagedenic ones, and to bring the patient's health into a more deranged and debilitated condition.

I prescribed for her, therefore, a draught of two ounces decoct. sarsæ, with three grains of the hydriodate of potash, to be taken three times a day, with full diet, and one pint of porter. The sores were at first poulticed, but afterwards the tepid water dressing, and latterly the red lotion, were applied.

Jan. 1st.—The above plan has been continued to this date, and the woman's general health is now very much improved, and the sores are nearly healed.

16th.—The hydriodate was discontinued for a few days, in consequence of some febrile disturbance having occurred; but it was soon renewed, and the doses gradually increased.

Feb. 17th.—All the sores are completely healed, and the rupia cured; her only complaint is of some tenderness in the cicatrices.

19th.—Discharged cured.

CASE IV.—*Secondary Syphilis, Tubercular Eruption, Rupia, and Ulcers.*

Elizabeth Wilson, æt. 42, admitted January 31, 1839.

About three years ago, she had a discharge, whether from gonorrhœa or chancre, we know not; but as the discharge was followed by a bubo, which suppurated and burst, the presumption is, that she had some kind of primary sore. These complaints, she says, were communicated to her by her husband, and were cured by the same kind of medicine which he took, and which, from its having made her mouth sore, and loosened her teeth, we may conclude was some preparation of mercury.

Two months after this, she was attacked with pain in the lower part of the tibia, and in the knee-joints. The interval which occurred between the primary and secondary symptoms, I may remark, corresponded in this instance to what is most usual; that is, the secondary began within the period comprised between the end of the sixth week, and that of the third or fourth month, from the time when the primary complaints were cured. About a year ago the right leg ulcerated, the ulceration having been preceded by pustular or tubercular spots, according to the description which she gave of her case. There are also some ill-conditioned secondary ulcers on the right arm, forehead, and neck, with an eruption here and there, presenting the characteristics of venereal rupia.

This woman was not in quite so reduced a state of health as Mary Ford; but she was weak and sallow, and had had no menstrual evacuation for a twelvemonth.

Feb. 1st.—She was put upon the same plan of treatment as Mary Ford, and to the ulcers the water dressing was applied. This day the menses returned; and why they did so directly she had come amongst us I cannot undertake to explain.

8th.—The dose of the hydriodate was now increased to five grains, and the red wash put to the sores, which were already considerably improved.

27th.—The above medicines discontinued on account of headache.

March 2d.—The compound infusion of gentian, with tincture of calumba, directed to be taken in the dose of $\frac{3}{4}$ j. thrice a day.

8th.—Still making progress to a cure. Ulcers all better, and the rupia nearly gone. In order to expedite the successful termination of this case I adopted the plan, particularly commended by Sir R. Carmichael, viz. that of exhibiting small doses of mercury, when the health is improved and the disease on the decline. I directed

this woman, therefore, to take, in addition to the compound infusion of gentian, with tincture of calumba, three grains of the blue pill and five of the extract of guaiacum every night, made up into two pills.

Under this treatment a cure of all her complaints, except one or two small ulcerations on the leg, has been accomplished; and these are now dressed with a weak creosote lotion, and are healing.

Had mercury been freely employed in either of the last two cases, directly after the admission of the patients into the hospital, reduced and disordered as their health then was, I have no doubt that both these women, instead of being now cured, would have been in their graves, or upon the verge of them, with extensive phagedenic ulceration, and implication of the bones of the nose, palate, and other parts. Hundreds of such melancholy cases produced, as I firmly believe, by the injudicious use of mercury, did I see many years ago in the venereal wards of some of the hospitals of this metropolis.

While I am drawing your attention to these facts, it is fair to state, that cases of primary and secondary syphilis do occur, in which, if you persist in abstaining from the use of mercury, the disease lingers for an indefinite period, and you would not be doing justice to your patients were you still to adhere to the determination of not employing the mercurial treatment; and this is the truth, notwithstanding the full admission of the fact, that in time a cure might be effected by other means, or even by nature herself. But the cases to which I here allude, are not the sloughing and phagedenic forms of syphilis, nor those in which the skin exhibits rupia and secondary ulcers, nor others in which the bones of the nose, palate, and other parts, are attacked by caries and necrosis. I would add, that mercury should be suspended and avoided, not only in all these examples, but in every case of syphilis attended with extreme weakness and emaciation, loss of appetite, sleepless nights, quick feeble pulse, palpitations, and severe derangement of the whole constitution. First try, gentlemen, at all events, to get the general health into a better state; observe what changes such amendment will cause in the specific disease; and then employ mercury, or not, according to circumstances. Frequently, it will not be required; and if judged necessary, it can now be tried with more safety to the patient than at an earlier period.

N.B. Since the above lecture was delivered, Charles Rawlins has got into robust health; but a tubercular eruption on the arms and face has made its appearance,

and a small portion of the original sore is not yet healed. As this man has not taken a grain of mercury, it is an excellent opportunity of observing what course the eruption will follow under the non mercurial treatment.

THE MEDICAL MISSIONARY SOCIETY IN CHINA.

On the 21st of February, 1838, a public meeting, called by T. R. Colledge, Esq. and Dr. Parker, was held in the rooms of the General Chamber of Commerce at Canton, for the purpose of organizing a society which had been long contemplated, called the Medical Missionary Society. Resolutions relating to its object, officers, members, meetings, library, anatomical museum, qualifications of the medical men employed, hospital register, foreign agents, and a public address, were read, discussed, and adopted.

The following is an abstract of the address:—

The object of this society is to encourage the scientific practice of medicine and surgery among the Chinese, and to extend to them some of those benefits which science, patient investigation, and the ever-kindling light of discovery have conferred upon ourselves. To restore health, to ease pain, or in any way to diminish the sum of human misery, forms an object worthy of the philanthropist. But in the prosecutions of our views we look forward to far higher results than the mere relief of human suffering; we hope that our endeavours will tend to break down the walls of prejudice and long-cherished nationality of feeling, and to teach the Chinese that those whom they affect to despise are both able and willing to become their benefactors. In the way of doing them good our opportunities at present are few; but among these, that of practising medicine and surgery stands pre-eminent. Favourable results have hitherto followed it, and will continue to do so. It is a department of benevolence peculiarly adapted to China. Could we dispel their fears, and make known to them the true character and desires of civilized western nations, many are sanguine that a more friendly policy would be adopted towards us. We have called ours a Missionary Society, because we trust it will advance the cause of missions, and because we want men to fill our institutions, who, to requisite skill and experience, add the self-denial and the high moral qualities which are usually looked for in a missionary. By the result of such an agency the way will be paved to a higher place in the

confidence and esteem of the Chinese, which will tend to put our commerce and all our intercourse with this nation on a more desirable footing, and to open avenues for the introduction of those sciences and that religion to which we owe our greatness and our happiness. There are also other advantages: among the first we would refer to the benefits which are likely to result to medical science by cultivating it in China. All acknowledge that each country is characterized by the prevalence of certain maladies, and the partial or complete exemption from others; and that the contemplation of diseases influenced by climate, locality, and the general habits of the people, is highly interesting and instructive. To secure the advantages desirable from such a view, a book will be kept in all the institutions connected with the society, into which all important cases will be entered with a notice, not only of the disease and treatment pursued, but also of the province, habits, and other circumstances bearing on the history of the individual. Such books will in time be curious and valuable documents. And from the extensive *materia medica* of the Chinese we may also look for many valuable additions to our dispensatories. Another advantage will be in the increased acquaintance with China and its people. The information obtained in this way will be of the highest value to all interested in this country, and such as can be depended upon; for a sick man will often deal frankly with his physician, however he may be disposed to conceal facts or garble his statements with any other person. A third advantage will be, the extension to the Chinese of medical knowledge. Facts shew that Chinese parents are not altogether blind to the desirableness of placing their sons in our hospitals, as there are three under tuition in our institution at Canton. Young men thus instructed will gradually be dispersed over the empire, dispensing benefits wherever they go: their success will render them respectable, and, of course, redound to the credit of those from whom they have learned the art. The effect of such influences will be silent, but powerful. These are some of the results anticipated, and it will not be denied that they form desiderata of no ordinary interest and importance. The state of medical science in China shews the value of our efforts. The Chinese doctors are usually unsuccessful literati, and admit their ignorance of medical science, especially of surgery and anatomy. An amusing and ridiculous compound of astrological dogmas, and dissertations on the influence of the elements, takes the place of the well-established principles of

physiology and chemistry now received in the west. Nearly all adopt the common vagaries concerning the pulse, which is their infallible key to every ailment. Their knowledge of the circulation is very doubtful. No argument is needed to prove the importance of effecting a revolution in their erroneous systems.

ABSTRACT OF THE REPORT OF THE CASES THAT HAVE BEEN ADMITTED AT THE OPHTHALMIC HOSPITAL, AT CANTON, UNDER THE CARE OF DR. PARKER.

During the period of two years, from 1836 to 1838, 4575 patients have been received.

1. *Diseases of the Eye.*

These, from their great prevalence, have been the most numerous. Chronic, acute, and purulent ophthalmia, cataract, entropia, amaurosis, opacity and vascularity of the cornea, nebulae, lippitudo, granulations, staphyloma, pterygium, and allengo, are, judged from the reports, the most general. Hundreds have presented, whose sight, from want of timely assistance, was totally extinguished.

2. *Diseases of the Ear.*

These, perhaps, are as numerous as those in the eyes, arising from the pernicious practice of barbers, who introduce a sharp cutting instrument into the ear, by which violence is frequently done to this delicate organ. Only a few have been admitted.

3. *Cutaneous Affections.*

In no country in the world are diseases of this class more numerous and aggravated. Few as yet have been under medical treatment.

4. *Miscellaneous.*

Abscesses, tumors, scirrhus, hare-lip, ulcers, hernia, ascites, and several other minor cases.

Several patients with enlarged spleens of a very aggravated character have appeared, and Dr. Parker is inclined to think that these affections are numerous in China.

Abdominal tumors and scrofula are also common. The nature of the former cannot be satisfactorily determined, as autopsy is not allowed at present.

Facts are constantly occurring which shew the increasing confidence of the Chinese in foreign surgery, and the widening extent to which the knowledge of the operations has spread. As illustrative of the former, Howqua, the senior Hong merchant, has presented £60 to the institution; and in proof of the latter, numbers of all ranks have come long journeys to avail themselves of its benefit. Besides operations on the eye, several others have

been performed. The following are two of the most interesting, condensed:—

No. 3488. *Cartilaginous Tumor.*

May 22d.—Woo Pun, æt. 41, a shoemaker of Pwan-yu. *History.*—About seventeen years since a small hard tumor appeared upon the left side of the neck; it gradually increased in size at first, but for the last ten years its growth has been rapid, and from its magnitude become very cumbersome.

Present state.—The tumor is as large as his head, and pendulous. From the submaxillary region it extends backwards over the carotid artery and external jugular vein, and forwards to the opposite side of the trachea; its greatest diameter is downwards. Having been perforated by the escharotics of a Chinese practitioner, it emits a most offensive discharge from the aperture, which is half an inch in diameter, and as regular as if formed by a drill. The pressure of the thumb makes no impression upon the tumor. His constitution has begun to suffer.

On June 19th, at one o'clock, the tumor was removed in about five minutes. Several veins of considerable size were divided. The chief artery, which was a superficial one, by care was not divided until the tumor was dissected out, and thus very little blood was lost. The patient bore the operation with great fortitude. The greatest circumference of the tumor was found to be two feet, and its weight seven pounds.

At three and five o'clock his symptoms were favourable.

At nine he did not breathe so easily as usual, but made no complaint. His brother was depended upon to watch him, and send for me if any change occurred. At one o'clock A.M. I was called, and on arriving found the patient labouring for breath. He was very bloody, and had evidently made a great struggle without success to loosen the bandage. The pulse was just perceptible, and his extremities cold. The neck was instantly freed of the roller, and stimulants administered, with hot bottles to the feet, &c. The man soon rallied, and his dyspnoea subsided. The cause of the suffocation was evident: the oozing of the blood had increased, and not having free outlet, accumulated in the inferior edge of the wound, and pressed upon the trachea. His brother, instead of watching, fell asleep. After reapplying the dressing the patient had a comfortable night, and in one month was perfectly recovered; he now enjoys excellent health, and evinces unbounded gratitude.

No. 3790. *Sarcomatous Tumor.*

June 19th.—Yang She, æt. 20. The

formation of this tumor commenced ten years ago, and from its rapid increase in size soon became burdensome, especially the last six years. It is pendent from the chin and larynx, and extends as far down as the umbilicus. The weight being thus sustained by its attachment, which is not more than two inches in circumference, the patient constantly sits in a bracing posture, to prevent its drawing down the head. The natural features are distorted, from the cheeks being drawn tense; and the muscles of the back, being in constant action, are preternaturally large. A native practitioner applied a ligature, which has produced a scar; but from its not being sufficiently tight to strangle the tumor, it did more harm than good. She is in her fifth month of pregnancy.

Both herself and friends being very anxious to have it removed, I, with the approbation of several medical gentlemen of the H.E.I.C.S., complied with their wishes; and the operation was performed in a few seconds. Two arteries of considerable size required ligatures; some of the veins were larger than the jugulars. The integuments, fascia, veins, and arteries, formed the principal attachments. The operation was borne without a murmur. In seventeen days she was discharged well. Her first attempts to walk were awkward, having lost so much "ballast." About five months afterwards she returned in excellent health, bringing a robust little son. Her features have assumed very much of their natural form.

A peculiarity of the Medical Missionary Society in China, is, that it addresses itself to the consideration of *all*.

The man of science and the philanthropist are here interested, and a rare opportunity is now offered to them of doing good—of enjoying the felicity of imparting to others, without diminution to himself, some of his richest blessings. All are earnestly invited to co-operate in accomplishing a great immediate and positive good, and to aid in uniting to the great family of nations this long severed and secluded branch, and in introducing among this vast people not only the healing art, but in its train the sciences and all the blessings of Christianity. But to the medical profession in particular this Society commends itself, both to their judgment and patronage; and it is trusted that it, as well as the scientific public in general, will manifest their interest in an enterprise so valuable as it doubtless will prove to the medical and commercial worlds. A large and commodious building, capable of containing 200 patients, has lately been purchased at Macao, on behalf of the Society, by the President,

T. S. Colledge, Esq., and will only require about 300*l.* a year for its support—a sum exceedingly small to secure the objects which it has in view. The directors of the London Missionary Society had long been honoured by the distinguished exertions and agency of the late eminent scholar and missionary, the Rev. Dr. Morrison; but, since his death, finding it impossible to introduce Christianity into China by clerical agency alone, have determined, after mature consideration and the evidence of its practicability and propriety, to sustain two medical gentlemen suitably qualified to practise their profession in all its departments, especially surgery, in China; and such have been lately appointed.

Persons subscribing 2*l.* annually will be considered members of the Medical Missionary Society during the period of their subscription. Donors to the amount of 20*l.* will be constituted members for life.

Subscriptions and donations in aid of this specific object, will be thankfully received by the Secretaries of the London Missionary Society, Blomfield Street, Finsbury; Messrs. Hankey and Co., 7, Fenchurch Street; Messrs. Magniac, Smith, and Co., London; or T. Thomson, Esq. Royal Bank, Edinburgh; or Messrs. James Ewing and Co., Glasgow; and will be acknowledged in the Annual Report of the Medical Missionary Society.

B. H., M.R.C.S.

NOTES OF

PROFESSOR JÜNGKEN'S CLINICAL REMARKS.

Characters of various Discharges from the Eye.
—*Fistula Lacrymalis.* — *Cataract.* — *Cod's Liver Oil.*

H. M., aged 65, has a cystic atheromatous tumor on his forehead, swelling of the lacrymal sac on the right side, on which the lower eyelid is much excoriated; he has also greyish yellow cataract of the left eye. On making pressure on the sac, a large quantity of acrid pus discharged itself; general health pretty good.

Professor Jüngken said that it was very important to attend to the nature of the secretions of the eye, as doing so materially assists our diagnosis in many cases. Thus in the catarrhal forms of ophthalmia the secretion is mild, and hardens into broad yellowish crusts; in the scrofulous it is acrid and irritating; while in the rheumatic clear hot tears shoot periodically from the eyelids, and in pure rheumatic inflammation never contain the least portion of mucus. In like manner,

the treatment of inflammation of the lacrymal sac is to be regulated according to the nature of the secretion. Thus, where the secretion is mild, and arising from chronic catarrhal inflammation, the use of a solution of one grain of sulphate of zinc in one ounce of water, varied with the use of weak aqua sapphinea, is sufficient, and will generally produce a cure; but if the tears are hot and clear, and rheumatic inflammation be present, blood-letting and active measures are required. Then, again, if the secretion be purulent, and the sac is once in a state of suppuration, it must be laid open. Nearly the same rules apply to the treatment of true fistula lacrymalis, in which the nasal duct is always implicated, and very generally from extension of the inflammation from the lacrymal sac.

The great object in treating fistula lacrymalis is to restore the nasal duct to its normal condition if possible. Of all its varieties, the most easily cured form of obstruction is, where the nasal duct is blocked up with mucus. In that case the application of slightly astringent lotions is generally sufficient. They should be dropped in between the eyelids at the inner canthus; the use of a syringe is not only unnecessary, but generally prejudicial, by destroying the tone of the puncta lacrymalia. In another form of obstruction, which is analogous to stricture of the urethra, and is the result of more acute inflammation, the sac must be opened and the nasal duct perforated by some body, such as cat-gut, &c. which must remain in it till the passage is re-established. But in a case like the present, where there is every reason to believe that the mucous membrane of the lacrymal sac is destroyed, and replaced by fleshy granulations, and that the nasal sac is quite impermeable, there is no chance of being able to restore the parts to their healthy function. The remains of the sac must, therefore, be obliterated, by laying it open and cauterizing it, and also taking care that the wound heals thoroughly from the bottom. One would, *a priori*, expect that the eye would, after the obliteration of the sac, be constantly subject to lacrymation. But it is not so in practice to any really inconvenient degree; certainly not in many cases which have come under the lecturer's notice; and if the patient will, from time to time, press the tears from the inner canthus of the eye, he will scarcely be at all annoyed by this cause. Professor Jüngken then laid open the sac with a small narrow-bladed scalpel, ascertained by trying to pass a sound, that the nasal duct was quite impermeable, and then cauterized freely the interior of the sac with nitrate of silver.

(The case proceeded most favourably, the wound being dressed from its bottom with red precipitate ointment, and in a couple of days the the excoriation of the eyelid was gone.)

Professor Jüngken then went on to remark, that seeing there was already cataract of one eye, he should have hesitated to cure the fistula if there were not the atheromatous tumor remaining on the man's forehead; no one could entertain a doubt that the cataract, the fistula, and the tumor, were owing to the same state of constitution. It was often very dangerous to remove atheromatous tumors from the heads of old men. He remembered many cases, particularly one of an old officer, in which several such tumors had been removed, and in which cataract had come on within a year. He had no doubt that the two facts stood to each other in the relation of cause and effect. He should not enter at present into the causes of cataract. The yellow hard cataract of old men was generally the result of gouty inflammation. In such cases the operation usually indicated was that of extraction. He should give a few practical remarks on the operation.

Under ordinary circumstances, where both eyes are affected, it is best to operate on both eyes at the same time. From the result of very many comparative trials, he had a great preference for making the section through the lower half of the cornea. The lens escaped with less injury to the eye, and the wound healed more readily, than when it was made through the upper half. The great mistake in operating was in making the section too small. It should include, at least, half the cornea. If the point of the knife get involved with the iris, the operation should be proceeded with as if nothing had happened. The bad effects of cutting away a portion of the iris were small, while the partial or entire withdrawal of the knife was most injurious. When the arcus senilis should happen to be present, the section was to be made through it, as the deformity of the scar would be the less. It was quite a mistake to suppose that the existence of the arcus contraindicated the operation of extraction. The appearance in question might possibly be owing to some change in the contents of the canal of Schlemm. This, however, he merely threw out as a hint.

[The canal of Schlemm, discovered by the Berlin professor of that name, is a minute circular canal, situated at the point of union of the cornea and the scleroticæ. It is not to be confounded with that of Fontana. Has it ever been demonstrated in this country?]

To snip off or touch with caustic a pro-

trusion of the membrane of the aqueous humor, is as absurd as to do the same to a hernia.

If a child has violent pholophobia, or shyness of light, and will not allow the surgeon to open its eyes on any account, be sure there is not much mischief within.

Nothing helps so much to make conjunctivitis chronic as the too early use of stimulant lotions, and washing the eyes with cold water.

The following case is merely given to show the confidence felt by Germaus in the efficacy of cod's liver oil:—

C. S., aged 17. All the signs of serofula very marked; his face almost square; enlargement of glands about the ear; has ectropium of the right under and left upper eyelid, caused by the scars of serofulous ulcers. His forehead, the side of his nose, the upper and inferior jaws, and left elbow, covered with ulcers communicating with dead bone.

Professor Jüngken said that it was out of the question to attempt any thing just now with regard to the ectropia. The object, for the present, must be to improve, if possible, the general health of the patient: when it was improved, something might be done for the affection of the eyelids, although they would be the very worst cases for operation, as there had been such actual loss of substance. Three tonics, iodine, iron, or the oleum morrhue, might be given. Professor Jüngken had of late seen such benefit from its use, that he should order the patient to take a table-spoonful of the oleum morrhue three or four times a day. J. M.

April 4, 1839.

LARGE DOSES OF ACTIVE REMEDIES.

M. FORGET, professor in the medical school at Strasburgh, has lately published, in the *Bulletin de Thérapentique*, several interesting cases, shewing the *tolerance* of some remedies in extraordinary doses.

CASE I. *Tartar emetic.*—A robust butcher, aged 40, labouring under acute articular rheumatism, took tartar emetic in a potion, first in the dose of eight grains, then ten, fifteen, twenty, thirty, forty, sixty, and seventy-two grains (a drachm), and this without any disorder of the intestinal canal, or any other bad symptom. The tongue was moist, but whitish; the patient always ate quarter diet, but became disgusted with the potion, and it was discontinued. Thus in the space of ten days, he took, without inconvenience, about three drachms of tartar emetic. Never-

theless he had a relapse of the rheumatism, but was cured by colchicum wine.

CASE II. *Kermes mineral.*—A man, aged fifty-five, emaciated by a chronic disease of the chest, not being able to bear a potion containing six grains of tartar emetic, took four grains of kermes instead, which produced an inclination to vomit. The next day he took six grains; a dose which was increased to fifteen, thirty, and seventy-two, without any bad symptom; but the remedy was discontinued, having no effect on the congestion of the bronchi.

CASE III. *Pomegranate root bark.*—A girl of four-and-twenty, fair, and of a lymphatic temperament, had suffered from tænia since her childhood, and frequently passed fragments of the worm in her stools. She took two ounces of the bruised bark of the pomegranate root boiled in two pounds of water, at thrice, with half an hour's interval between the doses, but without effect. The dose was now increased to three ounces, and two tapeworms were expelled; so that in two days, and without any abdominal disturbance, the patient took the decoction of five ounces of the bark of pomegranate root.

CASE IV. — *Ioduret of starch.*—Dr. Buchanan, of Glasgow, in 1836, published, in the LONDON MEDICAL GAZETTE, some remarks on the exhibition of this substance in the enormous dose of 72 grains and more, without any bad symptom.

M. Forget tried this remedy on a youth of 17, labouring under lymphatic turgescence, with ganglionic tumors of the parotids, scrofulous ulcers, &c. The iodine was first given in the dose of 24 grains, with an ounce of starch. The iodine being triturated with a glass of water, was carefully mixed with the starch, and being then diluted with a pound of decoction of rice, was taken in the course of the day, in four doses. The ioduret of starch was borne perfectly well, and the dose was increased to an ounce and a half, two ounces (containing 48 grains of iodine), and two ounces and a half. The feces were of their regular colour, and the urine, when treated with nitric acid, gave a yellow tint to white paper, or a deep blue when the paper was previously covered with starch; hence it appeared that the ioduret of starch was wholly absorbed. The dose was increased to three, and then to four ounces (containing 96 grains of iodine), but without lessening the disease. The patient now became disgusted with the remedy, and it was discontinued. In forty-eight days he took 139 ounces, or nearly nine pounds, of ioduret of starch, containing 3336 grains, or nearly six ounces, of iodine; being nearly sixty-six grains a day, of this active substance.

CASE V. *Bleeding.*—A patient, aged 30, of a splendid constitution and sanguine temperament, was attacked with violently acute articular rheumatism. Thirteen general bleedings of twelve ounces each, and 125 leeches or cupping glasses, abstracted at least fourteen pounds of blood in fourteen days; ten of the general and three of the local, bleedings were performed in ten days, without the slightest fainting, the slightest *souffle* in the carotids, or the least œdema of the extremities. The patient's convalescence was rapid, and in three months he had recovered all his vigour.

We agree with M. Forget in thinking this case quite an exceptional one; and although the severity of the symptoms, and the strength of the patient's constitution, may have justified these evacuations, yet as the author ascribes the fortunate termination of the disease to the use of mercury, we should be reluctant, even in similar circumstances, to push bleeding so far.—*Gaz. des Hôp.* Feb. 19, 1839.

[We entirely agree with the *Gaz. des Hôpitaux* in these observations on the last case, and would apply them to those in which tartar emetic and kermes were pushed so boldly. The patients had a happy escape of it, and that was all. Even the bark of the pomegranate root is said to have produced bad symptoms in large doses. Magendie, however, orders a decoction, made with two ounces of the bark, to be taken in a day (*Formulaire*, 8e édit. p. 381), which is about eight times the ordinary dose. He says that the bark is often mixed with that of box and other plants. The experiments with the ioduret of starch are curious; for though iodine is temporarily decomposed by starch, it is still carried into the blood, as appears from Dr. Buchanan's account (*Med. Gaz.* vol. xviii, p. 515,) as well as M. Forget's case. By giving iodine, in this form, Dr. Buchanan thinks that its irritant or corrosive action is avoided, while it produces the same alterative effects, but with greater energy, from the augmented quantity. On the whole, we believe that bold practice does harm ten times for once that it benefits; but in a tentative art like ours, even the rashest experiments should be registered—for warning, if not for example.—*Translator*]

PITUITARY GLAND.

RATHKE has lately traced the origin of the pituitary gland to a tubular prominence from the membrane of the cavity of the mouth. In many animals, and particularly in mammals, a short time before the formation of the palate,

there is seen, far back in the cavity of the mouth, below the base of the skull, an irregular roundish depression in the mucous membrane, but which, at a later period, is not distinguishable. This is the first stage in the formation of the pituitary gland. As it increases in depth, it passes through the layer of formative tissue at the base of the skull, obliquely upwards and backwards, and, after some time, forms a short blind tube, with a very wide aperture. At a later period there forms, before its entrance, a semilunar fold of mucous membrane, which, as it increases in breadth, covers it like a valve from before backwards. As this takes place, also the tube narrows at its aperture in the mouth (as the swimming bladder does in its relation to the alimentary canal), and at last the hole completely closes, and the (now) pituitary gland becomes a perfectly cranial organ.—*Rathke, in Müller's Archiv. Hft. v. 1838.*

BLOOD-GLOBULES OF THE CAMEL AND ALPACHA.

At the *séance* of the Institute, of December 30th, MM. Milne Edwards and Isidore St. Hilaire presented their report on the investigations of M. Mandl, on the structure of the blood-globules of various animals. They confirmed his assertion, that of all that he had examined (including many of the rarer mammalia), those of the dromedary and alpacha alone presented any other than the circular form; and that these were elliptical, their diameters being in the proportion of 1-235 to 1-230.

STATISTICS OF ST. PETERSBURGH.

THE *Abeille du Nord* gives the report of the Prefect of Police of St. Petersburg for the year 1838. It appears from this document that the population of the capital is 469,720, among which are only 136,000 women. The number of births was 10,437, and the deaths were 7,275. During the whole year there were only seven murders and thirty-four suicides.

Among the food consumed were 136,000 oxen, 48,000 sheep, 28,000 calves, 20,000 pigs, 68,000 fowls, 98,000 head of game, &c., besides 10,000 cartful of fish during the seasons for fasting.

Brandy was drunk to the amount of 28,000*l.*, and corn brandy—the favourite beverage of the Russian peasant—to the amount of 320,000*l.*

In the month of August, the small-pox ravaged several quarters of the town, and

attacked persons who had been vaccinated. In other respects the sanitary state of St. Petersburg was very satisfactory.—*Gazette des Hôpitaux.*

LECTURES
ON THE
CHEMICAL HISTORY, PATHOLOGY, AND
MEDICAL TREATMENT
OF
CALCULUS,
AND THE VARIOUS DISORDERS OF THE
URINARY SYSTEM.

By DR. VENABLES.

Diuresis saccharina—continued.

HENCE it appears that chyle, under ordinary circumstances, does not contain sugar in any great quantity; but, under certain derangements of the digestive functions, a chyle, with a large quantity, may be prepared and poured into the blood; and if the kidneys, as seems now the favourite doctrine, are to be regarded merely as percolators of the blood—for every constituent, healthy or morbid, has been either found in the blood, or its presence there rendered highly probable—we can have no great difficulty in reconciling the presence of sugar in the urine. It would, however, be very satisfactory, and certainly offers an interesting field for investigation, to determine, not only the presence of sugar in the blood, but the variety of saccharine matter to which it is most analogous, and whether it ought to be attributed to an intermixture of chyle of the same nature. We know how readily the different species of organic matter are converted into each other; during germination, for instance, the albuminous and amylaceous principles of the cotyledons are respectively converted into gum and sugar. The pulps of fruits, too—apples, for instance—become sweet; and during the process of malting, the starch is

converted into sugar. It is also well known in culinary concerns, that the starch of potatoes becomes, partially at least, converted into sugar on exposure to frost. But with the nature of the process by which these conversions are effected we are wholly unacquainted, and in like manner we are unacquainted with the minute operations by which similar conversions take place in the animal body. But from what has been advanced, it will be evident that the digestive organs are much in fault, and that, as already observed, an unhealthy chyle probably is thrown into the blood.

We have already stated, that the blood mixed with the fresh chyle passes into the right side of the heart, and from thence into the lungs, where very important changes are effected. First, the chyle is converted into blood, and the blood itself purified for circulation through the different organs. Two causes may operate here: first, the impurity of the chyle itself; secondly, an irregular sanguification in the pulmonary organs. Dr. Prout, however, does not consider the kidney wholly free from irregularity; he says, "but the kidneys, also, are undoubtedly involved in it; and as the natural action of these organs, as will be more particularly noticed presently, is of a disorganizing character, these undo what little had been done by the assimilatory organs, and the result is, that the alimentary matter is thrown out in the crystallizable form." From all that has been advanced, therefore, it appears tolerably well settled that the first error is in the digestive functions; next, perhaps, there is some derangement in the respiratory functions—a view supported by the frequent tendency to pulmonary diseases in diabetes; for in the great majority of cases the diabetes becomes complicated with pulmonary disease, mostly of a phthisical character. Lastly, the kidneys themselves, if they have

any action at all, seem to participate in the general degeneration.

Prognosis.—In diabetes the prognosis should always be unfavourable. We have already shewn that a saccharine state of the urine may appear either with or without diuresis. It is the latter, perhaps, which is more manageable. The cases which I have mentioned were kept stationary for a considerable time. The gentleman, however, died, I understand, not very long afterwards from a pulmonic attack, and, from all I could learn, of an inflammatory character, arising from exposure to cold. We must, however, bear in mind, that perhaps a mere saccharine uræsis is but the incipient part of the disease, and that unless great care be taken, a severe diuresis may easily be superinduced; and this is certainly a very formidable condition; therefore, even in the better forms, the prognosis should be guarded, and, when favourable, it should be only conditionally so. When, however, diuresis has been fully established, with a saccharine state of the urine, we must not hold out any thing like a favourable prospect. Although Dr. Prout does not consider a mere saccharine urine dangerous, yet when completely established as diabetes, it may be considered as one of the most formidable diseases to which humanity is liable.

Diabetes, however, may last for a considerable time without much alteration, and, as already stated, does not seem to prove fatal of itself; such an event mostly attending other diseases which supervene—such as phthisis, dropsies, or malignant diseases of various forms and characters. Therefore, so long as there appears to be no tendency to any of these complications, we may encourage the patient; and yet it is right to recollect, that diabetic patients who are also affected with any disease of the bladder, are apt to die suddenly with affections of the head, of an apoplectic nature. Upon the whole, a mere saccharine state, uncomplicated with diuresis, is not so very dangerous; complicated with diuresis, it becomes much more so; and if attended with any organic disease of other organs, or shew any tendency to such, there is much more cause for alarm; and, under all circumstances, we must keep in mind the natural tendency, even of the milder forms, to assume the true and severe diabetic character, with ultimately all the irremediable affections with which it becomes complicated.

Treatment.—On this part of the subject I fear there is but little to offer satisfactory. I believe the most authentic reports go to shew that nothing like a radical cure, nor indeed any thing like even an approach to it, has been effected. I am

aware that there have been many cases of cure recorded, and a number of remedies have been extolled as capable of producing these beneficial results. However, I need scarcely tell you that not one of these is satisfactory, because the only analogy between these cases and diabetes is the increased flow of urine. But an excessive discharge of urine may arise from so many causes besides diabetes, and many such are nothing more than mere temporary irritation, and which give way to almost any treatment, or even cease spontaneously, that we must look upon these cases as widely differing from the disease we are considering. I therefore consider no reported case satisfactory, unless the characters of the urine have been fully ascertained and stated. Not long since, a gentleman brought me some urine passed, as he asserted, by a patient suffering from diabetes at an hospital where he was a pupil. The patient had been passing several (I believe ten or twelve) pints of urine in the twenty-four hours. The specific gravity was stated to be 1030. The specimen brought to me was, however, only 1010. Of course I need scarcely tell you that diabetic urine never falls so low, and that this circumstance itself would have been sufficient to prove the case of a different description. Yet this case was considered as one of diabetes, and looked upon as an instance of a cure. Perhaps the utmost that can be expected from medicine, at least in the present state of our knowledge, is a mitigation of the more urgent symptoms, or the keeping them stationary.

Aretæus says, that diabetes is but a variety of dropsy, differing only in the part from which the humour flows*; and therefore he states that the remedies useful in dropsies are indicated here†. But we do not find very satisfactory statements in the ancients, and it is not improbable that they have confounded diabetes with diseases of a different character, much more frequently than the moderns. The treatment of a disease, the nature and pathology of which is involved in so much obscurity, and of which so little is really understood, it is evident cannot be established upon any fixed or philosophical principles.

When considering the morbid anatomy, pathology, and the immediate seat of the disease, it was shewn how little assistance was to be derived from all that was known for certain upon these points. Therefore

* *Τῶν ὁσίων ἰδὲν τοῦ διαβήτεω πάθος, αἰτίη καὶ διαθέσι· χῶρη δὲ μοῖνη διάφορον, ἔνθα τὸ ὕγρὸν ἐκρέει*—De Curat. Diuturn. Morb. ii. cap. 2.

† *Ἔστι δὲ τα ἅκεα ἐς τὴν ἐπισχεῖν τῆς ξυντηξίως τα αὐτα τοῖσι ὕδρωσι.*—Ibid.

all that can be done is to meet the most urgent symptoms upon general and established principles. "With respect to the treatment of diabetes," says Prout, "this has been as various as the opinions respecting its nature; and perhaps there is no disease in which so much mischief has been done upon false principle, and by random experiment, as in this. For my own part, I have no hypothesis upon the subject, and therefore shall proceed to lay down such a plan of treatment as seems to be best sanctioned by general principles and experience*."

The next urgent symptoms, and which cause the greatest distress, are those which arise from the general irritation of the nervous system: these are the febrile heat and its associates—dry, harsh, and rough skin. A question, therefore, of great moment first presents—how far blood-letting is applicable to the relief of these symptoms. It will be recollected that it has been shewn that care and attention will discover a diabetic condition—that is, saccharine urine—when the general observer will pass over the same unnoticed, until irremediable ravages have been made in the system. Now it is with the first class of observers only that the propriety of blood-letting can be at all a question, because it is only in recent cases, and before the vital powers have been completely exhausted, that this remedy can be admissible. And even in these it does not seem warranted, unless the symptoms have assumed a sufficient acuity of character. "In cases of recent occurrence, and of an acute character, there cannot be a doubt about the propriety and even necessity of general blood-letting, which may be repeated as often as the circumstances of the case may seem to require†." If, therefore, we find feverish excitement with high arterial action, a hard and frequent pulse, and especially if there be indications of any local inflammatory condition, bloodletting should be practised to an extent commensurate with the severity of the symptoms. Sometimes, too, blood-letting is necessary to relieve a mere plethora of the system; and although such a state is sometimes superinduced by habitual blood-letting, and which, therefore, is not to be recommended, yet the relief of the plethora by a well-timed and well-regulated venesection is often very beneficial, and, indeed, absolutely necessary. A local condition—a frequent consequence of plethora—often requires the vigorous adoption of the same means; this is congestion. Plethora, however, differs from

congestion, inasmuch as the former is a preternatural abundance of blood, whereby the larger trunks are unnaturally distended, and the vital or circulating powers oppressed*. This is evidently to be relieved by removing a portion of the circulating mass in the first; and in the second, by endeavouring to prevent any re-accumulation. Congestion is a sort of stagnant accumulation of blood in the small vessels—more particularly the veins—of the congested organ. As this preternatural accumulation frequently arises from a plethoric condition, and too great impetus of the circulating fluid, therefore one means of relieving it consists in diminishing the velocity and force of the circulation, which is best done by the abstraction of blood. To relieve the local plethora, leeches, cupping, and counter-irritation, are the principal means. It has been stated that sometimes the kidneys have been found in a congested state, and this is indicated by pains in the loins alternating with occasional ease, a sense of weight, lumbago, and sometimes tenderness on pressure. In such cases the cupping glasses should be applied to the loins, or leeches, and their repetition will depend upon the urgency of the symptoms, and the relief obtained.

Blisters are valuable remedies in cases of congestion; but from the irritation which cantharides produce in the kidneys, they do not seem so well suited to the cases under consideration. Instead of blisters, therefore, I generally prefer mustard cataplasms to the region of the kidneys, or a solution of ammonia in water or alcohol, or ammonia applied in the form of a strong liniment. But in many cases, instead of the loins, there is a sense of fulness and of burning heat in the stomach. In some there is a tenderness either in some particular spot, or extending over the whole epigastrium; and in some this tenderness is confined entirely to the scrobiculus cordis, and which the patient dreads to let you touch. In such, I need scarcely observe that the local means should be applied to the affected part.

As the bowels are usually constipated, they should be kept open; and this should be effected by the mildest means; and those aperients which exert a diuretic operation—the saline purgatives, for instance—should be avoided. Perhaps there is none better suited to our purpose than castor-oil: the action may be promoted by the occasional administration of an enema. These means will all of them tend

* On the Diseases of the Urinary Organs, p. 72.

† Ibid. p. 73.

* Plenitudo ad vires vocatur talis sanguinis abundantia, qualis vires moventes opprimat.—*Conspect. Med. Theoret. cap. xvi. 524.*

to reduce plethora, and to relieve congestion.

There are other means, however, and which, though applicable to other cases, seem to be highly prejudicial here—that is, mercury. This mineral seems to exert a very deleterious influence upon the kidneys, when they are at all the seat of disease. I have already brought under your notice instances in which morbid conditions of the urine were superinduced by the exhibition of mercury; and many have occurred in which ulceration, schirrus, and other malignant diseases of the kidneys and bladder, have been the result of a free use of mercury, where a tendency to some of these forms of urinary disease existed. Prout states that saline purgatives, and such as are likely to act as diuretics, should in general be avoided, “as should mercury, which seems capable of doing much mischief in this disease, more especially when pushed to any extent*.” Still although, as a general rule, mercury is not suited to this disease, yet there are occasions, as Prout himself admits, which not only admit, but absolutely require, the alterative operation of mercury; but it may be laid down as a rule, to which, perhaps, there is no exception, that salivation is decidedly injurious.

With the view of obtaining the alterative effects of mercury, it naturally presents for inquiry, what pharmaceutical preparation is best adapted for the purpose. Dr. Prout proposes the *hydrargyrum cretæ*. But this preparation contains very little—sometimes none at all—of the oxide of the metal upon which alone its efficacy depends. The more active, as the oxide, chloride, and some of the salts, as the acetate, phosphate, &c., are too active and virulent, at least they are apt to bring on salivation, with mucous ulcerations, which are not only positively prejudicial, but prove highly injurious, by the reaction which the highly irritable state of system so superinduced exerts upon the primary disease; and it is often very difficult to avoid salivation in such habits even from very small doses of mercury, and administered with the utmost caution. I have myself found the oxymuriate or bichloride of mercury not only the most manageable, but the most efficacious, form

for exhibition in such cases. In hepatic affections, and in those of the mucopulmonary membrane especially, the latter, attended with great prostration of strength and purulent exudation, I know of no remedy more efficacious. The best form is that of solution combined with a narcotic, as opium*. The formula below I have found extremely efficacious, and I have proved its value, by administering it with success when the other most approved methods of treatment had been adopted under my own superintendence in vain. There is also an advantage in this formula, that the bichloride may be exhibited with many of the vegetable tonics, and the excess of hydrochloric acid will prevent, or at all events obviate, those reactions which would render the combination unchemical, and probably so far inert†. But although there may be occasions to justify a resort to mercury in alterative and harmless doses, yet it is to be clearly understood, that nothing but absolute necessity can authorize our resorting to this mineral; and if my views be just, the bichloride will be found the most manageable, and the most innocent preparation.

Another remedial means of obviating plethora are emetics in nauseating doses. The effects of nausea have been already stated, and they are found to reduce the phlogistic diathesis, and to diminish plethora—agencies readily reconcilable to those who know that nausea reduces the force and frequency of the pulse, and prevents the formation of blood, as well by preventing assimilation as by promoting absorption. The exhausting or debilitating emetics, as they are named, are the most efficacious, by their influence on two

* In Irritation of the mucous lining of the bronch, attended with the utmost prostration of strength, the expectoration of large quantities of pus, and hectic fever with night sweats, I have found the following very beneficial:—R. Hydr. Bichlor. gr. j.; Acidi Hydroch. dilut. dr. ss.—dr. j.; Morph. Hydrochlorat. gr. j.—gr. iij.; Oxymerc. Simp. Mucilag. Acaciæ, aa. oz. ij.; Vin. Ipecac. dr. ij.; Aquæ Destillatæ, oz. iv. Dos. oz. ss. ter 4ve in die. The object of the diluted hydrochloric acid is to prevent any decomposition, especially if distilled water should not be used; and should we wish to add any of the vegetable tonics it would obviate any unchemical reaction.

† It has been stated that Sir Astley Cooper extolled the agency of bichloride of mercury with tincture of bark in scrofula, and when objected to him that the astringent matter of the bark would decompose the bichloride, replied, “Be that as it may, but tincture of bark is quite inert without the assistance of the bichloride, and therefore I shall continue the formula, notwithstanding its unchemical nature, or the decomposition that may ensue.” However, to obtain the effect, the bichloride must have been in sufficient excess to leave some of the salt in solution after all possible decomposition had been effected. I need scarcely observe, that a few drops of hydrochloric acid would have obviated every difficulty.

* Dr. Prout, however, qualifies the universality of this proscription, and admits, that as alteratives, their use may be occasionally beneficial. “The occasional use,” he says, “of saline and mercurial remedies, directed to the bowels and skin, may be proper, and even beneficial in some instances, particularly when the disease has been a little subdued. It is the too free employment of these remedies, and more especially of mercury, that I feel disposed to call in question. When mercurial alteratives are necessary, the *hydrarg. cum cretæ* seems to be the best adapted to the purpose.”—P. 74.

symptoms which we shall now proceed to consider.

Among the symptoms enumerated were excessive thirst and insatiable appetite. Thirst is one of the most distressing sensations; and the allaying the distress by excessive draughts of fluids is one means of aggravating the disease; nor, indeed, can the patient resist this propensity. Aretæus says that there is very great thirst; for he says the fluid voided dries up the body*, and therefore he says that we must apply our means to remove the thirst, not merely to appease it; for by drinking any thing, it excites the discharge of the urine, and liquefying the parts of the body, carries them off with it; and therefore he says our means must be directed to moderate or extinguish the thirst, not merely to assuage it by diluents, to which, he continues, no quantity of fluid is adequate, and that the stomach—the seat of the disease—is to be relieved†.

PHYSIOLOGICAL PROBLEM.

By WILLIAM GRIFFIN, M.D. Limerick.

Does suffering necessarily imply consciousness? Are sentient beings necessarily percipient?

NO. III.

IN prosecuting an inquiry of this kind, the physiologist no doubt finds himself continually staggered in the most apparently legitimate inductions by the recurring question, "Am I then to believe that an animal may experience a sensation, suffer absolute pain, without knowledge or consciousness of it?" Yet this is not more incomprehensible than other metaphysical truths when first proposed to the mind. The young philosopher is quite as much perplexed when he is first taught that all his knowledge of an external world of solidity and extension is not derived purely from the sense of touch; nor his

knowledge of figure, magnitude, or distance, from the sense of vision. Brown has, I think, very truly observed, that every original and accurate analysis of our sensations *must afford a result* that will appear paradoxical. Yet in this, as in every other correct analysis, the paradox begins to disappear in proportion as we learn to think clearly on the subject. For instance, when once we can conceive, even remotely, the possibility of a sentient existence as distinguished from a percipient one, it is not difficult to comprehend, that an animal to whom we deny consciousness of being may yet have a sense of being; and, in like manner, that although it may have no consciousness of pain, it may have a sense of pain.

The dogmatic manner in which metaphysicians have generally rejected the distinctions between sensation and perception, or consciousness, here suggested, even those persons who themselves applied the terms differently, and treated of them separately, was little to be wondered at before the extraordinary discoveries in the anatomy and physiology of the nervous system made of late years. But it certainly is calculated to excite some surprise that Mr. Grainger, who has lately written a very ingenious and interesting work on the functions of the spinal cord, and than whom no one was more fully informed of the apparently insuperable difficulties connected with the old opinions on the subject, should venture to dismiss the question in the same absolute and unargumentative manner. "It is, indeed," he says, "apparent that in every systematic treatise the most obscure statements prevail respecting the nature of sensation. Physiologists, although on these points they always speak in a most vague manner, seem to imagine that there are, in fact, two kinds of sensation—one which is attended with perception and consciousness, and one which is not; but it implies an absurdity to admit a sensation which is not perceived. In the case of vision, for example, the light falls upon the retina, and produces, by its contact, what is called an impression; but this impression is not converted into a sensation until it has been perceived by the mind." Again, he says, "If we free ourselves for an instant of all these confused notions of physiological writers, it becomes evident that there is but one kind of

* Δίψος δὲ τοῦ τέτοις μέζον, ἐκρέον γὰρ τὸ ὕγρον ἀναίνει.—De Curat. Diuturn. Morb. lib. ii. cap. 2.

† Ἐς δὲ τὸ δίψος μεγάλης ἡτρείης χρέος, τὸ δὲ γὰρ ἐν τῷ εἰδεῖ ἀλγέων πᾶν τῶν μέζον. καὶ ἡν πῶσι τὸ ὑγρον, προκλησὶς οὐρησις. ποτὶ καὶ ἐκρέον τὸ δὲ ξυπαγάγει τῆκον τα ἐν τῷ σῆνκεῖ. φαρμάκων ἂν ἀδίσων χρεος· δίψος γὰρ, μέγα, ἀκορίη ποίου. ποτον γὰρ οὐδ' ὅσον γίγανται δίψος ἄκρος. πάντα δὴ τῷ τῷ σλό-μακῷ ἀπρήγειν, ἔνθα τοῦ δίψος αἱ πηγὰι.—De Curat. Diut. Morb. lib. ii. cap. 2.

sensibility, *for the very term sensation implies something of which the mind is conscious*; thus, for instance, if I touch a piece of wood with the finger, a certain effect is produced on the ends of the sentient nerves, which is called an impression; and this impression, when it has been transmitted to the brain, is by the agency of that organ perceived, *and then, but not till then, sensation is produced.*" In these extracts all the assertions (given in italics) are mere gratuitous assumptions of the very points at issue. Not to go any further, if, as Mr Grainger states, when perception takes place, and not till then, sensation is produced, we may fairly inquire what earthly difference he makes between sensation and perception. If impressions produce no sensation until perception takes place, it must be something subsequent to, and arising out of, the perception not antecedent to it, as is usually presumed*; or it must be synonymous with it, and so superfluous. In such case, indeed, much needless difficulty and error would be avoided by always speaking of impressions and perceptions only. But it will be at once seen, by the observant reader, that the opinions Mr. Grainger considers so erroneous have arisen as legitimate inductions from facts and experiments, which, if not satisfactory, are at least more so than any others one can arrive at; while the assumed absurdity of these opinions is derived either from his own theoretic or preconceived notions. For example:—When once it was ascertained that sensation, to all appearance, remained uninjured after the destruction of the brain—the acknowledged organ of consciousness—it became evident that the sentient portion of our being—the sensorium—was very different from, and independent of, the conscious or mental portion, and that sensation could be no longer looked upon as a mere function of mind; yet Mr. Grainger asserts, as if it were almost a self-evident proposition, "that the very term sensation implies something of which the mind is conscious;" and upon this assumption proceeds unhesitatingly to strengthen the foundations of a far more difficult and unsatisfactory theory—that of Dr. M. Hall on the reflex function.

Considering, however, the very perplexed and vague notions of most physiologists on these subjects, it was perhaps not unnatural that those who found it impossible to conceive the independent existence of sensation and consciousness should seize with avidity upon the only other conjecture that made any approach to a solution of their difficulties. Extravagant as the notion might appear, that the attempts made by a brainless or headless animal to remove a source of irritation with its paws, just as if it had not been mutilated—the cries uttered by it when pinched, or when a hair of its whisker is pulled, as in the rabbit—or its dartings forward and endeavours to escape—should be considered as mere insentient phenomena, offering no indications of suffering, and produced by an independent reflex action of the cord, it seemed to present less difficulties than the more commonly received doctrine, that these cries and movements were voluntary, and yet persisted after the destruction of the only acknowledged organ of consciousness and volition—the brain; or that in the lower orders of animals, contrary to all analogy, consciousness and volition were transferred from the brain (the organ with which they are known to be connected in man) to the spinal cord. From all that has been already stated, it must occur to the reader that the perplexities in every view of the subject with modern physiologists have arisen from the vague and unmeaning manner in which the word volition has been applied. It is understood, and properly understood, to imply a mental effort; and so long as it was spoken of in connexion with consciousness or a percipient organ, the application was intelligible; but when the brain was gone, and, of course, perception and thought with it, volition was still spoken off in connexion with sensation. The motions which persisted after decapitation, it was said, were the result of sensation and volition; or, in other words, they were the result of a mental effort, after the organ was annihilated, in which it was acknowledged the animal's mind or perceptions, such as they might be, resided. If the plain and obvious inductions which the results of pathological observation as well as of experiments on living animals suggested, that consciousness and volition—the ascertained functions of the brain—were

* Reid says, "The impression made upon the organ, nerves, and brain, is followed by a sensation, and, *last of all*, this sensation is followed by the perception of the object."

extinguished with it, but that as the signs of suffering, the motions invariably resulting from pain persisted after the extinction, sensation must necessarily persist also as their efficient cause, almost all the difficulties which forced Dr. M. Hall into a new, and, I think, unsatisfactory hypothesis, would have disappeared. The actions of animals after decapitation would then have been attributed to the same influence—sensation, to which so many complicated muscular movements are attributed in the perfect or unimpaired animals, and they would have been denominated not *voluntary*, but *sentient* action; they would have been classed with the actions of respiration, coughing, sneezing, sucking, yawning, vomiting, &c.—with the motions of the apoplectic, of the acephalous infant, and with many of the movements performed in the state of reverie, or in profound sleep.

The extensive influence of sensation in all our muscular movements is so masked by the association of the will in percipient beings, that it is difficult to estimate it. Not only are the actions of respiration, coughing, sneezing, &c., wholly independent of the will, but even the artificial combinations of muscular actions created by it could never be accomplished without the aid of sensation, and are, it would seem, eventually placed almost entirely under its dominion. As a very simple, yet striking, instance of the manner in which mere sentient actions are overlooked in percipient beings, and attributed to volition, I may mention the case of a patient whose arm was paralyzed. By the utmost efforts of his will, made at my desire, he could not move it more than five or six inches from his body, and could not raise it at all; yet, whenever he was seized with a fit of yawning, his mother assured me both arms were extended, and raised freely above the head, but on no other occasions. The movements in yawning have always been considered voluntary, yet here all the efforts of the will were unable to accomplish what sensation accomplished easily and perfectly, proving that those movements are really sentient, and not voluntary.

That such movements are not the result of the reflex function any more than of volition, but are dependent on sensation, I cannot offer stronger proofs than those proposed by Whitt and others, so admirably

stated by Professor Alison, and so little affected by any arguments which Dr. Marshall Hall and Mr. Grainger have been since enabled to bring forward. Professor Alison states—

1st. That sensation, as a cause, is adequate to the effects ascribed to it, is manifest from the fact, that the changes in voluntary muscles, in involuntary muscles, and in secretions thus ascribed to sensations, are not only closely analogous to, but in several instances identical with, those which are allowed on all hands to be excited by emotions.

2d. That all such phenomena as we ascribe to sensation, co-exists in the animal system only with indications of sensation.

3d. That, in various instances, sensations may be excited by impressions made on *different* and distant parts of the body, and the actions which succeed them in these different cases are the same, which proves that these actions follow, not an impression or irritation of any particular nerve or organ, *but the excitation of a particular sensation*. This is illustrated by the very various modes in which the sensation of nausea, and the complex effects succeeding it, may be excited, and by the excitation of laughter on tickling different and distant parts of the surface.

4th. Conversely, when different impressions made on the *same* part of the body, excite *different* sensations, even although it be certain they are felt through the medium of the same nerve, they are not followed by the same action. Thus, of many sensations felt through the first nerve, very few only are followed by any diminution of the heart's action, or by retching.

5thly. When the mind is much engrossed, either by previous sensations or by interesting trains of thought, any impressions on the organs of sense are transiently and imperfectly felt; and in these circumstances it is observed that the actions in distant parts, usually following such impressions, are either suspended or imperfectly produced—a further proof that the intervention of the sensation is essential to their production.

6thly. The remedies found to be most effectual in stopping or preventing these actions, when in excess, are either such as make strong and new impressions on the organs of sense, thereby diminishing the effect of sensations already ex-

isting, or else such as blunt the sensibility in general, and so diminish all effects of sensation.

The incontrovertible inferences from these, as well as from the many other facts already considered, were gradually leading physiologists to the conclusions respecting sensation and consciousness which it is the object of the present pages to establish. It was beginning to be very generally acknowledged that the complicated actions of muscles in respiration, sneezing, coughing, vomiting, &c. were independent of the will; and that these, as well as most of those apparently spontaneous movements occurring in decapitated animals, were, however inexplicable it might be, the result of a persisting sensibility. The adherents of older opinions had retired from the field, their doctrines in no sense enabling them to offer an explanation of such extraordinary phenomena, when a new theory was proposed—new, not as regarded the fact of movements arising from a reflex action of the spinal cord, but of that reflex action being excited by the impressions simply, and not by sensations.

It is not my intention here to enter into a particular examination of the doctrine of the reflex function, as proposed by Dr. Marshall Hall, but merely to point to such general and important objections as seem at the very outset difficult or impossible to get over.

The theory of combined muscular actions excited by impressions on the extremities of nerves, without the intervention of sensations, necessarily supposes definite and direct connexions between the excitor and the reflex nerves in all cases. Yet Professor Alison has fully shewn that no anatomical discovery—no conjectural connexion of nerves in their course or at their roots—can account for the muscular actions which arise in obedience to certain irritations applied; these actions accompanying or succeeding one another in great variety, not according to the parts or nerves irritated, but according to the sensations excited.

It supposes the reflex action to be produced by the transmission of impressions through excitor or incident nerves, distinct from those of common sensation, and not connected with the brain, to reflex or motor nerves. This, if admitted, would oblige us to believe in the existence of a separate incident

nerve, connected, by means of a particular point of the spinal marrow, with several reflex nerves for every different combination of muscular action occasioned by irritation of any single part of the frame. It would oblige us to believe that in the fifth pair are bound up, besides the pure sentient nerves, one nerve for the reception of impressions of cold applied to the face, and connected with the phrenic and intercostal, by which the act of inspiration is performed; and also with the cutaneous nerves of the whole surface, by which a general constriction of the capillaries is produced; another for the transmission of irritations of the nostrils, connected with the phrenic and lower intercostals and lumbar nerves, by which the act of sneezing is performed; and so a new and distinct nerve for every new modification or combination of muscular action which can arise from varying irritations applied to it. The energy or extent of a reflex action may vary with the degree of irritation applied, although the irritation be transmitted by the same conductor; but the nature of the combination or of the sympathetic actions cannot vary, unless by the excitement of a new sensation.

To quote, again, Professor Alison's observations on Sir C. Bell's respiratory system of nerves, which apply as fully to Dr. Marshall Hall's theory, "It offers no explanation whatsoever why irritation in the fifth pair in the nose excites sneezing, while irritation of the same nerve in the cheek excites full inspiration only; and other violent irritations of the same nerve and same branches of it, excite no respiratory action whatever—why the nerves of the diaphragm and abdominal muscles act simultaneously in the actions of vomiting and of straining, but alternately in the actions of coughing, sneezing, laughing, weeping, &c.—or why the nerves of the diaphragm act alone in the case of full inspiration, whether from irritation of the fifth pair in the face or of the par vagum in the lungs—or why the nerves of the abdominal muscles associate themselves and act simultaneously with those of the muscles of the face in the actions of sneezing, laughing, weeping, but not in those of full expiration or coughing, or tenesmus, in which they themselves act with equal force—or why the laryngeal branch of the par vagum, which moves

the arytenoid muscles, acts in concert with the nerves of the abdominal muscles, and closes the glottis in the actions of vomiting and tenesmus, but escapes such combination in the actions of laughing, coughing, or sneezing."

The theory assumes that sensation is only contemporary or incident, and not an essential in these actions; but it is not proved that any of those reflex movements attributed to sensation can take place without its intervention, and seems probable only in very few.

It includes a rejection of the evidences of animal suffering which have been acknowledged by mankind in all ages, and which are assumed instinctively by the brute. It compels us to believe, that when mutilated animals are writhing in torture, their cries, their struggles, their well-directed and natural efforts to remove the instrument of torture, or to escape from it, are mere automatic movements, wholly unconnected with pain. It would, indeed, take away from every human being the proofs upon which the sufferings of his own fellow-creatures is inferred, beyond the mere assertion on their parts, if it was not that the natural signs of strongly felt emotions or sensations affect us instinctively, and far too powerfully to have their influence supplanted by the most specious reasoning.

Finally, if it were even admitted that the struggles and cries, and natural efforts of brainless animals to escape from torture, afforded no indications of sensation, it is not denied that the persistence of spontaneous motion is an incontrovertible proof that sensation still remains: so far from this, indeed, spontaneity of action is proclaimed, by Dr. Marshall Hall, as the distinguishing character of the sentient and voluntary system, as compared with the excitomotor. He says, unhesitatingly, "these latter are never spontaneous; they are always excited:" and, in illustrating the fact by division of the spinal cord in a frog, observes, "I divide the spinal marrow below the occiput, with these scissors: all is still. Not a trace of spontaneous motion. The animal would remain in this very form and position, without change, until all signs of vitality were extinct." I have already pointed out that Dr. Volkmann has found this assertion of Dr. M. Hall's to be erroneous. "If, after the first convulsive movements following decapita-

tion in the frog have subsided, and when the body is little irritable, it be extended on a hard surface, it will (he asserts) retain the position in which it has been put for five or ten minutes; when suddenly, and without the application of any external stimulus, it will draw up its thigh, and change the recumbent for the sitting position." But it is unnecessary to attempt determining this point by reference to experiments in which there can be a possibility of doubt, when we have the fact already stated, of the divided earthworm, before us. Fleuren's chicken, which lived ten months after its brains were taken out, it is said, never moved except it was irritated; but this is precisely what might be anticipated, in an animal so high in the scale of being as to have its ordinary movements more dependent upon perception and volition than upon instinct or sensation. In a purely sentient animal, however—in an animal without brain, or with a brain to which the sentient cord is little subservient—division of the body does not deprive the segments of the conditions essential to spontaneous motion. Its movements in the perfect state being the necessary result, not of perceptions and volitions, but of sensations; and their nature being determined by the quality of those sensations, there is little injury occasioned by division, except perhaps the destruction of some particular instinct, which, unlike common sensation in such animals, may be connected with some limited point of its organization.

After all that has been here objected to the doctrine of reflex motions from mere impressions, it is not my intention to deny the existence of such motions in any case. The contractions of the iris on the admission of light, of the lids in winking, and of the uterus after death, in those cases in which labour is said to have been completed in the coffin, are sufficient to prove that sensation is not, in all cases, essential to the accomplishment of the action which usually succeeds it. In all instances, however, in which reflex movements follow mere impressions, it will, I presume, be found that the connexions between the incident and reflex nerves are clear and direct, as in the several beautiful illustrations of such connexions given by Sir Charles Bell. The relations of muscular motion with the nervous influence, are, I believe, still far from being clearly de-

finer or understood; and there are yet many complications to be unravelled by the physiologist, before he can arrive at the simplicity nature's arrangement. The most numerous and complicated movements of the living frame, appear to be the results of sensations or volitions: some few, classifiable, no doubt, under some simple law, arise from mere impressions; and some, as the movements of flexion and extension, may perhaps be explained by the doctrines of antagonism suggested by Bellingeri.

[To be continued.]

OBSERVATIONS

ON

COMPLICATED SURGICAL INJURIES,

INCLUDING GUN-SHOT AND OTHER WOUNDS.

By RUTHERFORD ALCOCK, K.T.S. &c.

Late Deputy Inspector-General of Hospitals with the Auxiliary Forces of Portugal and Spain.

(As delivered in his Lectures at Sydenham College School of Medicine.)

I.—On Military Surgery and the general characters of Gun-shot Wounds.

I HAVE reserved some remarks on the more complicated and serious forms of injury to which the frame is liable until this period of the course, aware that they must naturally find place in a series of observations, which, at the beginning of the session, I promised to give on Military Surgery, on Gun-shot and other wounds and injuries, which play so prominent a part in the military surgeon's practice.

I should, indeed, consider a course of lectures on surgery imperfect which afforded no information on the nature and treatment of gun-shot wounds—a class of injuries met with from time to time, even in civil life—presenting particular features with which it is necessary you should be acquainted—and above all, affording the best field for the practice and the study of surgery in its highest forms, from their destructive and complicated nature. Whoever has been engaged for a number of years in active warfare, and seen much military practice, may fairly be allowed a voice of some weight in matters connected with surgery, especially those which relate to injury from external

causes—by far the most important and numerous class of surgical cases.

It is by no means my intention, however, to confine these observations merely to gun-shot wounds; their nature and treatment form but one among many important objects of attention to the military surgeon. Were his sole study or practice these, I should feel less inclined to speak highly of the opinions, the experience, and the skill of the medical staff of armies and navies.

There is no form of disease, nor kind of injury, which does not come under their observation and fall to their care. They constantly, in the discharge of their duties, mark the first inroads, as they watch the last effects, of disease in the human frame, and in every shape incident to man.

The physical and moral causes productive of ill health, and their modifying power on the actions of the system, on disease and injury, equally claim their attention, nay, often are urgently forced upon their observation.

The health of large bodies of men being confided to the military surgeon's care, and that for a long period—men and hospitals placed under his absolute control—he has peculiar advantages for observation on health and disease; and to preserve the one is a not less important part of his duties than to cure the other. In a campaign he is constantly called upon to rely on his own resources solely; to decide with promptitude and vigour on the nature and treatment of injuries of the most various and often fearful character; to organize hospitals—even to create materials for its administration; strike order out of chaos, or at least a state of things much resembling: for these and a thousand other efforts he is called upon, and he must display the necessary qualities, or at once make manifest his deficiency. A vigorous exertion of intellect under the most difficult and disheartening circumstances either becomes habitual to him, or a thousand eyes feel and mark the want of such qualities, and he sinks and must ever remain a mere dresser of sore legs and flesh wounds.

A scene, which passed before me in Portugal, in the year 1834, is still present to my mind. Shortly after an action in front of Santarem, on the 18th of February, I was charged with the service of the Ambulance hospitals of the Portuguese army in Cartaxo, where

the wounded, of all denominations, had been indiscriminately heaped together during the first and second days after the battle, in sad confusion and in a state of great destitution. French, Belgians, Portuguese, friends and enemies, Pedroites and Miguelites! It is not on the battle field, or in the struggle, that the horrors of war are felt: all the passions are there in play;—the hope of victory—the fear of defeat—the excitement of action—joy at success—grief or dismay at disaster, general and individual—all are so many safeguards against calm reflection. We experience any thing in the affray but disgust or horror. These are feelings reserved for the succeeding days while threading a difficult way among the remains of the dead, and the mangled bodies of the dying; but more than any where amidst the groans, the sufferings, and the helpless misery, that every where meet the eye near the scene of action, and in the crowded hospitals of the rear.

I have now seen war in nearly all its aspects. I have been hurried forward in a sudden advance, and borne back with the retreating, with the attackers and attacked; death and wounds in all their various and hideous aspects had even then been long familiar, and yet I confess my heart sickened when, with the greater part of the staff attached to me, I entered the first of the buildings, called hospitals, and endeavoured to carry prompt and efficient relief to the mass of suffering which, in some new shape, stopped my progress at every step. Limbs fractured and shattered even yet undressed; all in the most deplorable state: some on straw palliasses, others stretched on the stone floor and in passages. There was a deficiency of linen, of bandages, of splints, of every essential for their cure: want of attendance, of air, and the whole in a state of filth, which I will not attempt to describe. Add to all this an utter want of order; the shouts of the healthy mingling in horrid din and discord with the groans of the wounded, and a scene more harrowing can scarcely be imagined!

To introduce order among these elements of confusion was my task: and in a six years' military service, which seems now like one unceasing campaign—so arduous was its nature, so incessant were the conflicts—many such have fallen to my lot; and to meet such

exigencies, and provide a remedy at once quick and certain for such evils, must be the duty of every military surgeon. Do not imagine that only such things can be met with in foreign armies. Ask the surgeons of the Peninsular forces, in the old war, for a description of the first day after a battle, and from each you will obtain perhaps a more graphic and quite as startling a picture.

I know not whether any of you may contemplate a military career: some possibly may; and to prepare you for difficulties which otherwise might take you by surprise, and without the means of overcoming them, I have placed before you one such scene. Before I slept, aided by the exertions of an efficient and zealous medical staff, all had been attended to, and dressed—several amputations, urgently required, performed—the crowded passages cleared—fresh air and some degree of cleanliness ensured—a regular system and division of duties from the medical officers to the orderlies established. Silence and something like order prevailed, as a final result of the day's work.

The range of a military surgeon's duties, as that of his experience, is the most extended that ever can fall to the lot of a medical man; for this reason: though a rude and perilous school, in such wars as I have served, it is also the best that could be devised for enlarging and improving a surgeon's mind: it teaches him to think and to act with decision and energy, and thus rapidly matures the mental powers. While it gives wide experience to guide the decision, it inspires a confidence and nerve in the performance of operations which never fails the surgeon, and often must ensure the successful issue to the patient.

But I will not detain you longer on the general features of a military surgeon's duties—the advantage or the difficulties inseparable from them; but shall proceed to a few remarks on gun-shot wounds.

Gun-shot Wounds.

In no branch of surgery or medicine, perhaps, do the appearances of effects resulting from similar causes, vary so much as in gun-shot wounds. The variation of symptoms and appearances from the same effects is great; but this expands to an endless and ever-changing field of observation when the whole range of gun-shot wounds is considered;

for here we find every possible degree of injury; and perhaps it rarely happens that any two cases are precisely the same in every particular. Over the bed-side of the wounded there is always much to be learnt, however well we may be acquainted with the principles of the art, and the practice of the eminent military surgeons who have preceded us. It can never, therefore, be a hackneyed or exhausted subject, for it abounds in new forms and characters.

He who writes and speaks, particularly on this subject, from the experience of others instead of his own, M. Dupuytren well remarked, in his clinical lectures on the gun-shot wounds which occurred in July 1830, at Paris, can but coldly reproduce that which has already been before the world, and probably in a better form.

That I am not so speaking, in this valuable, and I believe, nearly unique collection of gun-shot injuries you see some proofs; and here are detailed notes of some six hundred cases—the subjects of my careful consideration—selected as the most interesting from among near three thousand treated under my own eye in hospitals, the service of which I directed personally. These merely of injuries; for of disease many thousands more have necessarily passed under my observation in those hospitals. I speak not here of many temporary periods of practice and experience amongst the Spanish and Portuguese wounded in their hospitals occasionally confided to my charge.

I allude to these things, I beg you to believe, not as an idle boast of wide experience, but that you may know I speak to you on the authority of personal observation and practice, on a subject requiring both for opinions to obtain any value. Neither have I any intention of merely bringing under your notice good and successful cases, to give *éclat* either to this class of injuries, or by reflection on myself. You will find good and bad mingled as they occurred—probably more of the latter may purposely be selected, as better proving many principles and precepts; for thus only can you receive correct views. Often more is to be learned from a failure, or from unsuccessful cases, than by more fortunate practice. The great and unprecedented success of Frère Jacques and Raw contributed but little towards teaching us the best mode of performing the operation of lithotomy.

I feel it a duty, now that I am engaged in a series of lectures, during which it will be necessary to bring before you continued proofs of pathological and surgical labours, conducted on no very limited scale, to render the merit where it is due, rather than to assume it all, illiberally and unfairly to myself.

For the evidences of scientific labours with which the table is covered, and the ample records of all the cases treated, I am much indebted to a medical staff, of whom it may be most truly said, as a body, they were unwearied in zeal and humanity. With courage to endure privation, and knowledge to perform their arduous and responsible duties in a most efficient manner, they formed a class of medical men possessing these qualities in a degree I would not willingly undertake to unite now, were I leisurely to commence the formation of a new and equally numerous staff. To Mr. Callander, the Inspector-General, who selected the staff for Spain, the highest credit is justly due.

I had many other duties besides those of the hospitals; one of the principal of which, in the various stations both of Portugal and Spain, I always personally directed; but in reference to all my pathological researches—that for which no time or labour of mine could suffice—the zeal and ability of those gentlemen around me amply provided. My directions were not followed as mere orders on military service, but with an active and scientific interest in their fulfilment and the results, for which I must ever feel grateful. Many are dead—victims to the trying and perilous service to which they unflinchingly devoted themselves. In one short winter I stood by the death-beds of eleven! Some few, it is true, are settled in London or the country, their success in practice already insured by the same exertions and character which distinguished them when serving with me; but many more are in different countries—not a few in different quarters of the globe; and thus, of the absent as of the dead, the justice rendered to them may never reach their ears, but that cannot affect the duty I owe them, not to profit by their unceasing and united labours without acknowledgment; and I have at least one pleasure in performing it, that my motives cannot be misconstrued.

This is rather of personal interest to myself, gentlemen, and I ought to apologize for detaining you; but I felt as these preparations brought vividly to my recollection years of mutual labour, difficulty, and danger, that I could not proceed with satisfaction until I had discharged a debt of conscience, and one of the few debts we remember with pride and pleasure.

Of gun-shot wounds generally it may be observed, that the velocity and force with which a ball moves, of directly influences the nature of the wound. Some curious instances of this have come under my notice. A private in one of the English battalions in Portugal received a musket-ball just above the nostril, which glanced upwards under the integuments, and presented at the inner angle of the eye, having been stopped by the bones of the orbit; yet, strange to say, the bones of the nose suffered but trifling injury, and scarcely any exfoliation took place. In another case, a sailor of the *Donna Maria frigate*, in the action of the 11th of October, 1832, was sent to me soon after the battle, his leg and arm having been amputated for severe injuries received by the bursting of a gun. On the first dressing I discovered some foreign substance in the thigh of the amputated limb, and, on making an incision, extracted a rough irregular piece of iron of considerable size, weighing nine ounces. The opening it had made on entering, seemed not large enough to admit a substance more than a quarter its size, and with but slight marks of contusion.

Balls sometimes make incised wounds. A sergeant, on the 24th of November, 1832, received a shot in the face. I did not see him on the field; but the next morning he was shewn to me, with exactly such a wound as a sabre would produce across the cheek bone and corner of the orbit, fracturing the bones in the same direction: the ball, most likely, having first struck the low wall behind which he was posted. The concussion produced was considerable; a high irritative fever came on, and he eventually died.

It is stated that a shot striking a muscle in action, will produce a greater constitutional shock than if it struck against the same part of the same muscle quiescent. Such an effect, it has seemed to me, might be explained by

the fact, that, to put a muscle in action, there must be increase of nervous influence direct from the brain. This is a point of interest only under one view—viz. that we may not form an erroneous judgement from the degree of shock evident in a patient who has received a merely muscular wound. The vast amount of nervous influence pervading every fibre of a muscle, must have become evident to all who have used the knife. I have seen, in an amputated limb, a quarter of an hour after its removal from the body, the parts, on being divided, put on a convulsive action, irregularly and violently contracting the whole muscle or muscles; and so distinct and strong was this action, that each fasciculus of fibres could be traced in movement, and that for several minutes together. A ball, therefore, that traverses only a mass of muscular fibres, may well produce a shock of the whole system; and this must evidently be greater or less also in proportion to the idiosyncrasy of the individual.

With respect to the appearance of the entrance and exit of the ball, there is more variety in the appearance of the latter than the former. I have seen, however, in a wound of the face, the the opening made by the entrance of the ball not only clear and incised, which is unusual, but so small that it was difficult to conceive the possibility of a ball having passed in. Generally the entrance of a ball is marked by a circularly depressed, torn, and contused opening, while the exit very commonly assumes more of the appearance of an incised wound—a sharp irregular line, frequently with everted edges.

Patients can generally give no information on this point. The surgeon, therefore, must decide for himself as to the entrance or exit, as well as the course of the ball. If the ball itself be forthcoming, much information may be gathered from it. I remember a case where it was a question whether the ball had penetrated the thorax; it was afterwards cut out at some distance from its entrance, presenting, as you see, a flattened, slightly convex, and grooved surface, plainly indicating that it had wheeled round upon the ribs. Here is a very curious specimen of a ball jagged and divided by the force with which it struck the lower maxillary bone; and you see part of the crown of a molar tooth firmly imbedded in it.

This ball entered the left angle of the lower lip, comminuted the left ramus of the lower jaw, and passing directly through the tongue, broke down the jaw-bone at the opposite side. It carried away the second, third, and fourth molar teeth of the left side, and the fourth molar and canine teeth of the opposite, fracturing the maxilla in four different places. The tongue was so much injured that it hung out at one side, of a purple colour. The neck, throat, and fauces, were also much swollen. The ball, at its first contact with bone, seemed to have divided into two portions; one of which cut through the tongue lower than the other, passed obliquely downwards, backwards, and behind the soft parts of the back of the pharynx. The swelling was carefully cut open, and a piece of bullet and the crown of a molar tooth extracted. I may mention that he died on the 20th day, and chiefly from extensive disease of the lungs.

It is often important to obtain clear ideas of the course a ball has taken; and in this matter the patient will sometimes entertain a very strong and erroneous impression. One of the most singular instances I remember was a soldier declaring he had spit out a ball which had lodged firmly in one of the cervical vertebrae, as you see by this preparation. On another occasion, an officer received a musket-shot in the flank, while turning to cheer a regiment on to the charge. I was by his side, and staggered at the same instant, under a violent shock caused, as I felt fully persuaded, by a ball through my knee. Having recovered in two or three moments from the first blinding and sickly feeling, I was well pleased to find that I had escaped with a grazing shot, and proceeded to see what was the matter with my companion, the Colonel. He had been carried a few yards down into a road, out of the shower of shot which had somewhat suddenly fallen upon us: thanks to the white breeches of the charging column. His mistake was a stranger one than my own; for when my forefinger was buried in the wound, following the track of the ball, he was giving himself no little trouble to convince me that the ball had not gone in, until I told him I thought it must, because—the point of my forefinger was four inches deep in his flank.

In fact, wounded men get all sorts of impressions, not only from balls, but about them. Nothing is more common than for a man to assure you he saw the ball drop after it struck him, or that he had picked it up, and persist in it, until, by the aid of such conjuring as a little judgement and a sharp knife will effect, the real Simon Pure is held to his eyes, still red and warm from his body.

If the ball only present an entrance and no other wound by which it could have effected its escape, the best mode of ascertaining its tract is to pass the finger gently and quietly into the entrance; and by a little management you gain very accurate information of the course, even if your finger will not reach the missile. This is a thousand times more decisive than a probe, and is quite as easy in any recent case; for wherever a musket-ball has passed, be assured the opening is large enough for most men's fingers, and is productive of just as little inconvenience as the probe. A ball will sometimes inflict even a deep wound, carrying in a part of the dress, and be brought out with it.

A number of slight shots, I am inclined to believe, are more dangerous to life than one of a serious nature. A soldier came under my notice with several flesh and tolerably superficial wounds on the back from slugs; a high irritative fever set in, and carried him off very rapidly.

Another similar instance occurred in a young recruit, who was shot on the 29th of September, 1832, several slugs lodging in his back; one, however, had injured the spine a little above the sacrum. The patient followed exactly the same course, only his sufferings were more protracted, instead of his death more promptly resulting from the more serious nature of the injury.

Gun-shot wounds upon ligamentous fibres and fascia, I am led to class among injuries the most painful and troublesome, and the least manageable. Major G., an aid-de-camp to Marshal Solignac, when serving in Portugal, received a shot in the leg, which carried the leather of the boot with it through the integument, injuring the tendon of the gastrocnemius, but not penetrating. It seemed a trifling wound, and I called it so; yet the agony he endured then, and the pain and inconvenience he has suffered since, long after the

healing of the wound, seemed altogether out of proportion with the extent of injury; so much so, that I am ready to allow he was not far wrong in a reproach he addressed to me somewhat bitterly, when he said, "The wound may be a trifling one to you, as a surgeon; but, by Heaven! it has never been a trifling one to me, the patient!"

From many instances that I have seen of the great, and more than once fatal, anguish occasioned by the presence of foreign bodies, I am inclined to go further to insure their extraction than is generally recommended. If the ball can be felt, it matters not what depth of muscular parts may lie between, I would have it extracted, and, if necessary, incisions made for that purpose. Two cases more particularly impressed this upon my mind.

The one was a private in an English battalion in Portugal, who, the 16th November, 1832, in a sortie from Oporto, received a musket-shot immediately above the right clavicle. He was brought to me on the field; and on introducing the finger, I could feel the ball with the extreme point, rather more than a finger's depth below the surface, slightly tortuous in its course obliquely across the superior part of the chest. I endeavoured carefully, but for a considerable time, to extract the ball, fearful, however, of using much violence, as the subclavian artery laid bare, was pulsating below my finger, and the common carotid equally exposed on the side. I failed in my attempts. He was conveyed to the hospital with a slight dressing over the wound; and the next morning, better provided with means and instruments, I renewed my efforts, and at length succeeded. He had suffered great pain during the night, and a high irritative fever had already set in, which eventually proved fatal.

A second case occurred in the same day, which terminated fatally also.

Lieutenant B. received a musket-shot in the calf of his leg. He was a strong athletic man, and had certainly the largest leg I ever remember to have seen. I could feel the ball with a probe, passed on my finger, about the centre of the calf, deeply imbedded on every side. The muscles were so powerful, and contracted so forcibly across the course of the ball, that it could only be reached by his standing exactly in the position

in which he received his wound, and then only by means of the finger. In this case, as in the former, I anxiously endeavoured to extract the ball by the opening at which it had entered; but the irksome position in which the nature of the wound obliged me to keep him, added to the pain he was suffering, and his own urgent and impatient entreaties, induced me to postpone any further operation till he was more comfortably in his bed. A few hours had scarcely elapsed before great inflammation and swelling came on, and the mere approach of my hand made him shriek with apprehension. Emollient poultices, fomentations, copious bleeding, &c. were directed, to reduce the inflammation, pain, and extreme irritability, which set in with great violence. I was taken ill myself the next day, and before I could leave my room he died. On examination after death, the ball was found flattened beneath the tendo-Achilles, having, in the short space of four days, worked its way from the calf to the heel!

I have always regretted I did not adopt a bolder and more decisive practice, and cut directly down through the muscles of the calf to the ball, making nearly the same incision I should have done without a moment's hesitation had the posterior tibial been wounded. In a similar case I would do so, especially where my patient was of a sanguineous temperament, "living hard," as it is termed, and consequently extremely susceptible of high inflammatory fever and local mischief, and more especially where the ball was in the neighbourhood of a deep strong fascia.

This is in direct contradiction—and therefore do I thus by cases insist upon it—to the precept laid down by Mr. Hunter, "that where the ball lies so remotely from the skin that it can only just be felt, and the skin itself is quite uninjured, no counter opening ought to be made. The wound heals better when the ball is left in, and far less inflammation takes place in the vicinity of this extraneous body than about the orifice of the wound." I am well convinced by all my experience, that the rule and the reasoning are alike founded in error, and calculated to produce disastrous consequences in practice.

The consideration of the last case also leads me to another point of no little importance in the treatment of

gun-shot wounds, viz. the early examination of their nature. In some of instructions I drew up for the guidance of the junior medical officers under my orders, when at Oporto, in 1832, I laid down the following rule, which every year's experience since has most fully confirmed:—

“In examination of wounds, never trust to any future moment for making it more carefully or maturely. The *first* is the best, and often the only one. The parts afterwards become swelled and inflamed, and the patient cannot bear the slightest touch; his future comfort and safety, therefore, often depend upon the officer who first dresses him satisfying himself completely of the nature of the wound. If this be delayed, both the surgeon and patient will have many vain regrets at a later period, even should a mistaken diagnosis not prove fatal, as may unfortunately happen; and, when possible, *the finger is the best probe to be used*: it is less likely to do mischief, and much more certain of conveying correct information.”

[To be continued.]

INTESTINAL GLANDS.

To the Editor of the Medical Gazette.

SIR,

SHOULD the following communication appear to you of sufficient importance, you will, by giving it a place in your journal, much oblige

Your obedient servant,

A. ANDERSON.

173, Hill Street, Glasgow,
April 13, 1839.

Being last winter engaged in examining the alterations which the glands of the intestinal villous membrane exhibit during disease, and having dried on glass a few specimens of Peyer's glands, I observed in some of them a structure which has not yet, I believe, been described. That the following description may be understood, I beg the reader who is not acquainted with the structure of these glands, to refer to the account given by Müller of their cells, and the coronæ of Apertum, which encircle and lead into them. At fig. 1, I have given a plan in section of one of these cells, along with the coats of the intestine and Lieberkühn's follicles,

penetrating about two-thirds of the thickness of the mucons membrane. As the villi are the most vascular part of that membrane, and as they do not exist over the roof of the cell, it follows that a congested gland should have a mottled appearance, from the vessels existing in greatest number between the cells.

When a gland so congested is dried on glass, and allowed to lie for several days, white opaque spots appear in the points, of fainter vascularity, or, in other words, on the roofs of the cells, so that the gland presents the aspect depicted in fig. 3. Since these spots are opaque, they are of course black by transmitted light; and when magnified, are seen to be formed by vascular-like bodies, ramifying to an extreme degree of minuteness (fig. 4, which was taken from a specimen where these appearances were more distinct than in that of which fig. 3 is a sketch.) The same thing may be observed in the solitary follicles of the cæcum and colon (fig. 2.) These ramifications are perfectly invisible till the intestine is quite dry. They are seen in perfection only when the gland has been inflamed; and if it be macerated for a few days before being dried, none appear.

I carefully, with a fine needle, turned off the roof of one of the cells, while still moist, immersed in water, and under the lens, so as to expose without injuring its convex bottom; and having then dried it, found that the ramifications were seen only round the edges of the cavity, and close upon the surface of the specimen, so as to shew that they exist near the free surface of the villous membrane, and on a level with the roof of the follicles.

They are not, however, confined to the last-mentioned part, for although they frequently cover it, yet they seem to extend outwards beyond its margins; and in the specimen from which fig. 4 was drawn, the trunks of larger size appear to be pretty much in a line with the “corona” of apertures already alluded to. This is more plainly the case in a specimen which I possess, taken from the very lowest part of the ileum: in this the follicles had an elongated form, and the trunks generally enclose a long oval. That they are not confined to the roofs of the cells appears also from their being distinct in the solitary glands of the colon, which, accord-

ing to Müller, have no roof, being open above. I have not yet been able to detect the ramified structure in the solitary glands of the small intestines. In the Peyer's glands of the cat—the only inferior animal which I have examined—it is distinct, but the branches seem to divide less minutely than in the human subject.

FIG. 1.

Section of Peyer's gland.

FIG. 3.

Peculiar appearance in the dried gland.

smallest venous branches are not filled, and in the intermediate spaces the vascularity is less minute, since the blood, conveyed into the villi by several arteries, is returned by a single venous twig, of comparatively large size, passing down the centre of each villus.

As to the nature of the peculiar structure I have now described, it is plainly in some way connected with the follicular apparatus, as it is confined to the Peyer's and solitary glands: the ramifications have much of the tree-like form of secretory tubes, and we are immediately led to conjecture that their function may be secretion. The circumstances of their being invisible in a piece of intestine which is moist, or in one which has been macerated, would seem to favour the opinion of their visibility being due to their repletion with some substance, opaque when dry, transparent when moist, and soluble in water; and as they are scarcely seen in glands which are not more or less inflamed, it is very probable that they are called into full action by disease alone. This appears to agree with the hypothesis of my friend, Dr. Staberoh, of Berlin, who

In a Peyer's gland well injected with size, minute arteries are seen branching very tortuously in the roof of the follicle, and covering the inner wall of the cell, so that, when the specimen is dry, they seem in some places to mix with the above-described ramifications; in a congested gland dried with the blood in its vessels this is not observed, as the

FIG. 2.

Same appearance in solitary follicle of colon: fat globules around the larger venous ramification.

FIG. 4.

Same magnified— $\frac{1}{2}$ inch focus.

supposed that, in irritation of the Peyer's gland, a peculiar substance was developed, which caused ulceration by the irritation of its presence in the tissues, and I possess specimens in which the roofs of the cells have been removed probably by this process. In others, a whitish matter fills the cell; and in several cases I have seen it disposed on its bottom in a distinctly stellated form. Whether this matter be poured into the follicle from the ramifications I know not. I have plainly seen openings on the inner surface of the cell; but, from their size and situation, they appear to be the internal mouths of the oblique canals into which the apertures, forming the external corona, lead.

This white matter being in the cells, exists close to the villous surface, and in minute quantity; but a superficial observer might easily mistake for a peculiar deposit the indurated, matted, vascular, cellular tissue, which in some instances attains a thickness of nearly one-third of an inch under the Peyer's gland, presenting, unless carefully examined, all the appearance of a mass of a totally different nature.

CASES OF OPHTHALMIA.

To the Editor of the Medical Gazette.

SIR,

THE following ophthalmic cases appeared to me at the time they occurred to be possessed of some interest. If you think they are likely to prove so to a portion of your readers, you will oblige me by inserting them in the pages of your journal.—I am, sir,

Yours respectfully,

JOHN WALKER.

Manchester, April 15th, 1839.

Paralysis of Motor Oculi Nerve.

CASE I.—Mary Davis, æt. 37, admitted an out-patient of the Eye Hospital, 23d of October, 1838. She states that four days since, on awaking in the morning, she was unable to elevate the upper lid of the right eye, which had been previously unaffected. She had been frequently troubled with giddiness, and some pain in the head. She has likewise a good deal of twitching about the muscles of the face of the opposite side, which has existed for some time past.

There is now a complete drooping of the superior eye-lid, and scarcely any power to enable her to raise it. The lid being raised with the finger, and being told to move the eye about in various directions, she is unable to do so, except outwardly. The pupil is dilated and immoveable. Vision is not much impaired, and no other mark of disease is discernible. She was ordered to be bled from the arm, *ad deliquium*; to take a calomel and jalap powder occasionally, and 10 grains of blue pill night and morning.

October 26th.—The giddiness is removed. She has some pain in the eye on moving it. With some exertion, she can now elevate the margin of the lid to the upper part of the pupil. The motions of the eye-ball are still much impaired. The pupil is somewhat less dilated.

Ordered a blister to the temple, to be kept discharging with the Ung. Lyttæ. Continue the blue pills as before. A dose of Sulphate of Magnesia occasionally.

December 4th.—The mouth has been kept sore for some time. She is much

improved. Can now elevate the upper lid almost as well as before, but cannot keep it up very long at a time. The motions of the eye-ball are now accomplished with some facility, and the pupil is more contracted.

From this time she gradually recovered, and was soon able to be discharged.

CASE II.—Mrs. F., æt. 40, applied to me on the 27th of November last. She states that about a month since she received a blow on the right eye, which rendered her faint and insensible for a short time. When she recovered, she found that she was unable to raise the upper eye-lid, in which condition she has continued up to this time.

Both eye-lids are now perceived to be almost in contact; the upper completely covering the cornea. She has not the least power over the levator palpebræ muscle, and, consequently, if she desires to expose the eye she is compelled to push up the superior eye-lid with her finger, on the removal of which it again instantly droops. The winking motions continue regularly with those of the opposite eye. On separating the lids, the pupil is observed to be a good deal dilated, but her vision is not much impaired. She is able to discern any object with this eye; but, after looking for a few seconds, she becomes sick and giddy, and can see no longer. She cannot move the eye-ball either upwards, downwards, or inwards. The external direction is the only one that can be effected, and this is its usual position.

She has experienced much pain about the forehead; first over the right eye, and since over the left. Occasionally she experiences a sense of vertigo. In other respects her health is good, although she is evidently a delicate person.

Ordered Empl. Lyttæ nuchæ applicand. Hydrarg. Submur. gr. iv. ter in die sumend.

Dec. 10th.—For several days past she has been suffering from ptyalism, her mouth being very sore, and discharging a watery fluid; she then left off taking the calomel. The ptyalism is somewhat abating. There is a slight improvement in the action of all the paralyzed muscles.

Ordered to take two purging pills, containing two grains of calomel, every or every other night. A blister to be

applied to the temple of the affected side, and the part to be dressed occasionally with Ung. Lyttæ.

Jan. 10th.—A very marked improvement is now observable. The upper lid is raised almost to the same extent as that of the other eye. She can move the eyeball, too, in every direction, but not quite to the full extent; it is still slightly turned outwards; the pupil is also more expanded than natural, but is considerably smaller than at first. Vision improves; the pain in the head has disappeared; her mouth has continued slightly sore up to this time, and the blister has continued to discharge.

Continue the pills, and let the blister be kept open.

From this period her recovery was rapid, and is now complete.

It is difficult to decide whether the symptoms in this case arose from an affection of the nerve within the orbit, or of the brain about its origin, or in the course of the nerve within the cranium. In every case of this description that I have met with (and I have seen a moderate number of cases), the symptoms always indicated more or less cerebral mischief. I can scarcely regard this as an exception. Dr. Mackenzie has, I apprehend incorrectly, stated that there is one form of this disease which may be regarded as rheumatic—a term which appears to me inappropriate when applied to the affection in question. He appears to consider it as an analogous disease to that which sometimes affects the branches of the portio dura when the side of the face is paralyzed; but the branches of the portio dura are very differently circumstanced to those of the motor oculi, the former being much exposed to the influences that bring on rheumatism, the latter scarcely at all so.

The disease generally yields to the kind of treatment pursued in these cases; when it is otherwise, it usually happens in persons who are difficult to bring under the influence of mercury.

Traumatic Cataract, simulating Fungoid Disease.

Louisa Stone, a delicate looking child, aged 3 years, was brought to me on the 17th of October last. It appears that about five weeks since, whilst attempting to sew, she accidentally pricked her right eye with a stocking-needle. For

some time afterwards no bad consequence was perceived, and her friends concluded that no injury had been done to the organ; but in about a fortnight after this the eye became inflamed, watery, and intolerant of light, and assumed a very dim and muddy appearance, which condition has remained up to the period when she was brought to me. She is now usually very drowsy, and appears to have much suffering in the eye, although her health is not otherwise much affected.

On examining the organ, there is considerable vascularity of both conjunctiva and sclerotica perceptible; the iris has a very dull, muddy appearance, the pupil being drawn to the inner angle, transversely oval in shape, motionless, and somewhat dilated. An opaque body is seen behind the pupil, having a yellowish brown colour. The cornea does not exhibit any appearance of disease. The whole eye has a disagreeably dull and unhealthy aspect, so much so as to convey the impression to my mind that the disease might be of a fungoid character. However, on the whole, I was inclined to regard the symptoms as arising from injury of the crystalline lens, which being broken up and pressing against the iris, had produced the inflammation then existing. The irregular form of the pupil—the result probably of the wound of the cornea and iris—rather tended to confirm this supposition.

Four leeches were directed to be applied around the eyelids, to be followed by the free use of an evaporating lotion. A powder of calomel and rhubarb to be taken every other morning.

22d.—The inflammation is somewhat diminished; she is able to expose the organ to the light, but it is still watery; she appears more lively, and suffers less pain.

Apply three leeches. Contin. Lotio.
Two grains of calomel to be taken each night.

Nov. 3d.—The opacity behind the pupil has now a more lustrous and shining appearance, and the idea of a fungoid affection again forcibly presents itself. It certainly exhibits a striking resemblance to it in the bright metallic reflection which is seen in that disease. She appears better in health, is more cheerful, and makes no complaint. There is still considerable vascularity of

of the outer tunics; but she exposes the eye more freely to the light.

A dose of calomel to be given every third or fourth night, with senna infusion on the following morning.

7th.—Has not exposed the eye so much within the last few days. It presents precisely the same appearance as at last report.

26th.—The vascularity diminishes, and the eye bears exposure better again. The organ looks more healthy, the shining appearance having vanished, and the opacity behind the pupil now resembles that ordinarily seen after injury of the lens.

Dec. 3d.—The vascularity is much diminished; the eye-ball, it is now evident, is beginning to absorb, being considerably shrunk, and feeling soft on pressure. Bears exposure to the light very well, and makes no complaint.

No further bad symptoms occurred. This case was at first, as well as during its progress, somewhat puzzling. It is easy to conceive that it might have been mistaken for fungoid disease, an operation might have been performed for its removal, and much unnecessary pain have been occasioned. I was much gratified when the eye put on the appearance of absorbing, having much feared that it would have taken an opposite course. It was quite possible that there might have been incipient fungus previous to the accident, and that the irritation succeeding it might have hurried on the progress of the malady.

Capsulo-lenticular Cataracts.—Extraction at a very advanced age.

Mrs. H., 87 years of age, has lost the sight of both eyes for a period of eight years. She is unable to discern any object, but can perceive the light of a candle, of the fire, or that of day. Her vision became gradually impaired, and without any obvious cause.

Dec. 4th, 1838.—On examination, it is evident that there is an opaque lens in each eye. The cataracts are of a pearly white, have a radiated appearance, and are nearly in contact with the posterior surface of the iris. The pupils are active and rather contracted; the anterior chamber small; in other respects, both eyes are remarkably healthy, with the exception of the cornea exhibit-

ing a broad *arcus senilis*. The eyes are, of course, somewhat sunk in the orbit. Her general health is very good, considering the advanced age.

Having explained to her the chances of a restoration of sight, from an operation, she became eager to have it performed. Although I was desirous of attempting the operation for extraction, there were some circumstances in the case which are usually regarded as unfavourable to that proceeding. The existence of the *arcus senilis*; the uncertainty of sufficient reparative powers, at such an advanced period of life; the small anterior chambers; the rather sunken eyes, were all of this character. As it was possible, therefore, I might be under the necessity of substituting depression for extraction, I determined upon applying the belladonna. This was directed to be done at night, and to be renewed in the evening.

5th.—This morning the pupils were found to be fully dilated; and, as had been previously agreed on, she was prepared to submit to an operation. As she was perfectly steady and composed, I resolved to attempt extraction by the upper incision of the cornea. She was laid upon a sofa, her head being raised and supported by three or four pillows. I seated myself on a chair behind her, and began with her right eye. Taking Beer's knife in my right hand, and raising the upper eye-lid with my left, the puncturation of the cornea was commenced at the temporal side, the knife pushed rapidly through the anterior chamber, the counter-puncturation being effected at the nasal side, and the instrument made to cut its way out so as to divide the upper half of the circumference of the cornea. Whilst this was in progress the pupil was observed to be rapidly contracting, and by the time the incision was completed it was as much contracted as if the belladonna had not been used. After the lapse of a few seconds, during which the eye-lids were closed, the proceedings were resumed. The curette was cautiously introduced under the flap of the cornea, and between it and the iris into the pupil, and the capsule gently lacerated. Slight pressure on the inferior portion of the globe was then employed, and the lens instantly protruded through the pupil and out of the wound. The lens was found to be exceedingly opaque, of a very firm consistence, and of a deep amber co-

lour. The opaque capsule was still seen to occupy the pupil, but was not interfered with. The eyelids being closed, strips of adhesive plaster were then placed over them, passing from the brow on to the cheek, so as to keep them at rest.

As she had suffered but very little from the operation on the right eye, I then proceeded to a repetition of the process on the left. Retaining my seat behind her, and supporting the upper lid with my right hand, the knife being in the left, I made a transverse section of the cornea, cutting out directly upwards, in the same manner as before. The cornea of this eye was much firmer, and the knife did not cut out with the same ease as in the other, but nevertheless the section was quite perfect. This eye appeared more sensitive to the knife than the other, but on the whole she complained very little. The pupil contracted in the same way, the capsule was opened, and the lens discharged with the greatest facility; the whole business occupying but a few seconds. The opaque capsule remained as in the other eye. The same dressing was applied. I advised that she should remain on the sofa, without being disturbed until evening, and then be taken carefully to bed.

5th.—She has had very little uneasiness since the operation; has slept well during the night. The plasters having become loosened were removed, and fresh strips applied.

7th.—Complains rather more this morning. Has been restless during the night from some uneasiness about the eyes, which she attributes to the plasters. The latter were removed, and a fold of linen, dipped in tepid water, applied instead, and ordered to be renewed occasionally.

9th.—Found her this morning sitting up, quite tired of bed, and fully determined to remain there no longer. The right eye looks remarkably well; the incision evidently healed; the anterior chamber distended with aqueous humour; a regular pupil, and no capsule to be seen. The left could not be seen so well, the conjunctiva being rather injected, and not bearing exposure to light.

15th.—There has been a little inflammation of the conjunctiva of both eyes during the last two days, for which, however, she has not required

any thing more than cloths dipped in warm water, and the internal exhibition of a mild purgative twice. She can now bear a slight exposure of her eyes to the light, and is able to perceive many objects, particularly such as are bright or shining.

21st.—Improves rapidly. The inflammation has very nearly subsided. The right eye looks exceedingly well. In the left there is a slight protrusion of the iris through the upper part of the cornea, so that the pupil is drawn a little upwards. The cornea of this eye was much tougher at the period of the operation, and the knife appeared to be cutting through cartilage, the point having been broken off.

From this time nothing particular occurred. The prolapsus of the iris was touched three or four times with the nitrate of silver, which completely removed it. She was soon able to read with cataract glasses. Her health has improved, and her countenance become more animated since the restoration of her sight, owing to her being able to move about better, and to take more interest in what is going on around her.

The result of this case is favourable to the operation of extraction, where it is often supposed to be contra-indicated. It is evident that the presence of the arcus senilis is no obstacle to the healing process*. The incisions in this case united without any difficulty; and that of the right eye it is now almost impossible to trace. The protrusion of the iris in the left renders it more apparent, but this is a common occurrence even in young persons.

The difficulty in cases where there is a small anterior chamber is, I think, very easily got over, by causing the pupil to be well dilated, there being then less chance of wounding the iris. Indeed I doubt whether, under any circumstances, dilating the pupil can do any harm; since, as happened in this case, it becomes again contracted almost by the time the incision is completed.

There seems an obvious advantage in making the corneal incision upwards, as respects the after treatment. The upper lid forms an admirable compress, nicely adapted to keep the surfaces of the wound in apposition; whereas, in

* See Jüngken's opinions in the last number of *GAZETTE*.—*Ed. Gaz.*

the lower incision, the wound is in almost immediate contact with the margins of both lids, and is liable to be irritated by their winking motions, which no dressings can entirely prevent. The greater steadiness of the patient, too, in the recumbent posture, is a matter of consequence, particularly to the unpractised surgeon.

The advantage of operating on both eyes at one sitting, is, that much time is saved in having but one confinement; the sufferings from which, joined to the debilitating effects of the treatment sometimes required, are often such as materially to undermine the constitution of the patient. Moreover, when one eye has been unsuccessfully operated upon, the patient gets mistrustful, and is apt to be more irritable. When both eyes are operated upon together, we can scarcely fail to succeed at least in one, and all further anxiety is at an end.

ANÆMIA CURED BY PROTO- CARBONATE OF IRON.

To the Editor of the Medical Gazette.

SIR,

IF you think the following case of sufficient interest for publication in the pages of your journal, I shall feel obliged by its insertion.—I am, sir,

Your obedient servant,

EDWARD JAY.

Davies's Street, Berkeley Square,
March 9th, 1839.

C. J., æt. 23, a young woman, of lymphatic temperament, slightly inclined to embonpoint, and with an hereditary predisposition to pulmonary disease, her mother and two sisters having fallen victims to phthisis; has been as long as she can remember the subject of bad health, which she ascribes to the fact of never having menstruated properly. Two years ago she was attacked with intermittent fever, and disease of the liver, both which diseases gave way under treatment, leaving, however, a state of debility, which has been increasing until it is arrived at its present alarming degree. There has been no appearance of catamenia for the last two years.

Present state.—The surface presents a general bloodless appearance, most striking on the conjunctival membrane, lips, and under the finger nails—in short,

wherever there is usually more colour; expression of countenance heavy and oppressed; constant pain referred to the vertex, increased by stooping, unrelieved by lying down, and worse always in the morning.

Although the surface of the body is cold, and there is a general feeling of chilliness, some increase of temperature occurs in the palms of the hands towards evening, succeeded by a slight tendency to perspiration; great dyspnea on making any exertion; œdema of the feet and ankles; constant dull pain between the shoulders and in the left hypocondrium. Restlessness at night, with disturbed sleep and frightful dreaming. Anorexia; tongue of a pale lilac hue; bowels costive; stools clay-coloured. Voice feeble; slight cough and trifling expectoration. No dullness on percussion beneath the clavicles. Respiratory murmur heard distinctly on both sides of the chest. Respirations frequent; action of the heart violent and frequent, and accompanied with a bellows sound. Pulse 90, and sharp.

For the relief of this condition she was recommended to take Ferri Carbon. in doses of ʒiij. ter in die . This she continued for more than a month, but without any benefit, becoming in fact worse; she then was under the care of a physician of eminence, who gave her cascarrilla with ammonia, and an aloetic pill at night. She persevered for some time without success, and it was resolved to give the iron in the following form; and as the anæmia might, perhaps, be connected with the remains of ague, quinine was added.

\mathcal{R} Acid. Sulph. Dil. gtt. xlv.; Ferri Sulph. gr. ij.; Tr. Lavand. Co., Syr. Aurant. aa. ʒss. ; Aquæ, ʒiiss. M. ft. haust. ter in die, c. Pulv. Sodæ Carb. gr. x., et in impetu effervescent. sumend.

\mathcal{R} Quinina Sulph. gr. ij.; Con. Rosæ, q. s. M. ft. pil. i. ter in die sumenda.

Also, the bowels were slightly acted upon by a night-pill, containing small doses of blue pill and Pil. Aloes cum Myrrha.

Soon after commencing this treatment the patient rapidly improved; perhaps the change was as striking as can be ever effected by medical means. Some colour made its appearance on the surface; the headache was gone, the

appetite good, and exercise was no longer attended with dyspnoea. After continuing some time, every symptom was removed, and she declared herself better than she could ever remember to have been. The catamenia have not appeared, but the probability is that they will, as their non-appearance undoubtedly was the result of deficiency of material for their formation. The interest of the case appears to be, that when the sesquicarbonate of iron failed to effect a cure, the protocarbonate was at once successful. It is also a question, whether at the same time getting rid of any effects of malaria by quinine, and re-establishing the intestinal secretions, did not assist? At any rate, the result was striking and satisfactory.

ON THE NEW VACCINE VIRUS.

MR. ESTLIN'S THIRD LETTER.

To the Editor of the Medical Gazette.

SIR,

As I have received an answer from the Registrar of the National Vaccine Establishment, in reply to my application for them to use the fresh vaccine lymph *for the purpose of distributing it free of expense* to those medical men who wished to have it, I shall be glad of permission to insert another communication in the MEDICAL GAZETTE. My request is refused, and I am therefore preparing a *letter of resignation* of the office (rather an onerous one) of distributing lymph to all who apply for it. For the last six or seven months I have been constantly engaged in this business; and I cannot but hope that, eventually, I may be in some remote way instrumental towards procuring the permission to medical men of having vaccine lymph circulated *free of postage* from all quarters, as well as from the National Vaccine Establishment.

I know not what *your* sentiments are with respect to the proceedings of the National Vaccine Establishment: to me it appears a most *inefficient* institution, though provided with means, and with abundant information, to be exceedingly useful in promoting a proper investigation into all the difficulties which surround vaccination. Under its present regime, with its meagre, indefinite Annual Reports, it appears to me an *incubus*

on the progress of vaccination in this country. I should be very glad, if it were in my power, to lend a helping hand in awaking this sleepy establishment, carefully, however, avoiding all allusions to, or reflections on, *individuals*. I know there are those of much influence in our profession in town, who, though unwilling, from various circumstances connected with the members of the Board, to take any ostensible part in finding fault, would be very glad to see a more efficient management pursued.

In the first volume of the MEDICAL GAZETTE is an editorial article which quite accords with my views: if such be yours, would not the present be a suitable time to renew such observations?

I doubt if there be any one subject of communication to the GAZETTE that meets with attention from *so many* readers as vaccination, and therefore it is that I feel less reluctance in being so frequent a correspondent upon it as has been the case latterly.

I purpose sending you a letter of four or five columns by the end of this week, or by Monday next, for insertion in the GAZETTE of Saturday week; and I have a communication from the Faculty of Medicine at Glasgow, in reference to the new virus, and containing some valuable observations on vaccination, which I think you would be glad to publish on the following week. I must, however, write to Glasgow for permission to make this use of it, and hope to forward it to you for insertion in the number for next Saturday fortnight.

I am, sir,

Your obedient servant,

J. B. ESTLIN.

Bristol, April 16, 1839.

FOURTH LETTER.

SIR,

HAVING received a letter from the Registrar of National Vaccine Establishment, in reply to my request that the stock of vaccine virus procured from the cow in August last might be kept at that institution, in order to supply those professional gentlemen who wished to make trial of it, I must trouble you with one communication more, probably a final one, in reference to this virus.

It will be in the remembrance of such

of your readers as have taken an interest in the subject, that in consequence of the numerous applications made to me for the new lymph, more numerous than probably I could continue to comply with, I wrote to the National Vaccine Board, requesting their aid in supplying the demands of the profession. My letter was dated November 23, 1838; and on the 14th of December, by desire of the Registrar, I sent several charges of lymph to be employed in establishing the new supply. On the 23d of January, 1839, an additional quantity was requested by the Board, which I also forwarded. On the 3d of this month (April) I received a communication from the Registrar, from which the following statement, being all that relates to this subject, is extracted:—

“I have the pleasure to inform you that we have duly tried the lymph which you were so kind as to send us, and that in four cases out of five we have succeeded in producing the true vaccine disease, and which in no respect appears to differ from that we daily witness from the employment of the lymph of this establishment. In two instances, however, the lymph taken from the above successful cases did not reproduce perfect vesicles; they were small, and without areolæ. I am instructed to add, that under the present circumstances the Board are not disposed to entertain any preference for your lymph, or would feel justified in substituting it in lieu of that which they are in the constant habit of using, and of which, consequently, they have a most extensive and satisfactory experience.”

The reference to the new lymph is concluded by the following extract from the letter of Plymouth correspondent to the Board, dated March 9, 1839:—

“Mr. Estling’s vaccine has been introduced here, and I have used it in two cases, but am not satisfied with it, and intend vaccinating with the true virus: many of the practitioners here have the same opinion of the Estling vaccine*.”

* As the Registrar has seen fit to send me such an extract from the correspondence of the National Vaccine Board, perhaps I may be excused for giving a quotation from one of my correspondents—the surgeon of two extensive medical charities, in one of our most populous towns, who vaccinated not *two*, but *two hundred* children, between January 28th and April 8th. He says, “Notwithstanding the *wise* letter of the Vaccine Board, with Sir H. Halford’s signature

That the new lymph should supplant the stock previously in use, I neither asked nor wished; but considering how great the demand for it had been, and regarding the National Vaccine Establishment as one intended to promote, in all rational ways, investigation into the subject of vaccination, it appeared to me not unreasonable to hope—I thought, indeed, that the profession had a right to expect—that the Board would employ the facility it possesses for extensive vaccination, and the privilege accorded to it by government, of receiving letters and sending lymph, free of postage, to meet the wish widely felt by medical men, and lend its aid to the experimental employment of a fresh supply of virus from the cow.

In this hope I have been disappointed; and if the grounds of the refusal are satisfactory to the profession generally, I have no right to complain.

I am, however, now desirous of considering myself released from the offer I made seven months ago, to furnish the new lymph to any professional man connected with an institution for gratuitous vaccination that applied for it. That offer has been extensively embraced, and I have sent supplies to Bangor, Barbadoes, Bath, Berwick-upon-Tweed, Birmingham, Bridport, Bridgend, Bridgewater, Cambridge, Chepstow, Douglas, Droitwich, Dublin, Exeter, Falmouth, Glasgow, Gloucester, Hull, Ilfracombe, Ilminster, Kidderminster, Langport, Liverpool, London, Malvern, Manchester, Maxstock, Nevis, Newport, Oxford, Plymouth, Plympton, Retford, Sidmouth, South Petherton, Stroud, St. Vincent, Somerton, Swansea, Stafford, Thirsk, Warrington, Warminster, Wincanton, Winchester, Worcester, York, and to numerous other towns and villages; besides to America, France, Switzerland, Portugal, and Madeira.

Having thus testified my desire to promote the interests of vaccination, and being denied that aid from the New Vaccine Establishment which I thought I might calculate upon, I feel myself

attached to it, about twenty to thirty medical men have now received the new virus, and the old stock at the Dispensary here is now obsolete. To-morrow the Hospital will receive the new matter, so that soon, all round this populous district, none but the new matter will be in existence; the hospital and dispensary being the only two places where vaccine inoculation is publicly done, from whence it is distributed to all the medical men around.”

entitled to retire from an office, which, though productive of much interesting correspondence, has not been unattended with trouble or expense. It is, I presume, unnecessary for me to add, that I have had no interest in the employment of the new lymph distinct from that of the profession and the public. I have declined all vaccinations but gratuitous ones (excepting in the families where I am the regular attendant), and I have freely given the matter to all who have applied for it.

In my former letters I have avoided giving any decided opinion with regard to the new lymph, and have withheld nothing that was unfavourable to it. I have been anxious to state the facts I had remarked, to induce others to make their own observations, and to have the experiments extensively made before any inference was drawn.

But having watched the virus through twenty-nine subjects successively (nearly one every week since the matter was procured from the cow), I have now no hesitation in stating that I consider it a valuable supply of virus, more energetic in its local and constitutional effects, and more inclined to produce vesicles resembling what cow-pox was many years ago, than that employed by the National Vaccine Establishment. It is so much estimated in this city, that I believe there is no other in use; and, as an institution has been established here, to be devoted solely to vaccination, we hope to be able to keep up the new stock.

What is the general opinion among the practitioners who have employed it in the numerous places to which it has been sent, I have had little means of ascertaining. I trust they will not withhold their views from the public. I presume, from the quotation sent me from the Plymouth correspondent of the National Vaccine Establishment, the Registrar considers the experience in the two cases referred to, and the opinion expressed by the writer, as evidence *against* the genuineness of the lymph: your readers must form their own judgment on this point. It is not impossible that even from Plymouth some opposing evidence may appear; and perhaps I may be allowed to adduce, as testimony of at least equal value, a published Report of the Chorlton-upon-Medlock Dispensary, Manchester, in which the decline in the activity of the

former virus is spoken of as having "been long felt by the medical practitioner," and the new lymph is described as "a present of no ordinary value; and, since writing the above, I have received a Report of the committee of the Vaccine Institution connected with the Faculty of Medicine in Glasgow, specially made in reference to the new virus, minutely detailing its effects, and designating it as "a great boon to the public and the profession." This document contains some most judicious observations upon vaccination.

Whether it be dependent upon a more cautious mode of vaccinating (the introduction of only a very small quantity of lymph into never more than two points of insertion), or upon any alteration in the lymph, violent local irritation and cutaneous eruptions less frequently accompany the progress of the vesicle at present than was the case six months ago; but the character of the vesicle is most satisfactory. On the eighth day it may be compared in form to a minute coil of inflated intestine: it has a pearly hue, with scarcely a line's extent of redness at its base—often none at all: it is solid to the touch; freely yields pellucid lymph when punctured in the centre; and is so little affected by the escape of its fluid contents, that I have charged thirty points from a single vesicle without any perceptible change in its size or shape. On the ninth or tenth day the areola comes on. Sometimes the crust projects from the skin on the subsidence of the areola on the fourteenth or fifteenth day, and falls off in about a week more: in many cases, however, it becomes rather indented towards the fifteenth day, very like an eschar made with caustic potass, and accompanied by a secondary attack of surrounding inflammation, of a more diffused character than the original areola; the crust is then separated, leaving a small but deep ulcer, that heals in a few days. And here I would express my surprise, that in the Report sent from the National Vaccine Establishment, the new lymph is spoken of as producing a disease "which in no respect appears to differ" from that which is daily witnessed from the use of the lymph usually employed there.

Most extraordinary, I am certain, will this statement appear to very many practitioners who have used the virus; and limited, indeed, must be the expe-

riments made with it for such a conclusion to be formed. Perhaps, however, the opinion of the Board is founded upon no more than the seven cases referred to in the letter of the Registrar, and the two cases from Plymouth. Very different is the experience with the new virus in this city. The only objection to it I hear of here is, its being much more active than the old lymph; and there are practitioners in other places who, from this cause, have thought it prudent to suspend the employment of it.

How far the introduction of a fresh stock of virus from the cow will have any influence in renewing the protecting power of cow-pox—which, of late years, it seems in some degree to have lost—I have not presumed to offer an opinion. It appears to me that one, and not an unimportant, step is gained, if this recurrence to the original source has procured a virus more energetic in its course, capable of retaining its infecting properties for a longer time, and producing a vesicle more resembling that which was seen twenty years ago, than the lymph in common use.

That the new virus possesses these points of superiority I have no doubt; and though I have before commented upon the late Report of the National Vaccine Board, I cannot conclude this letter without repeating my regret that, in the present unsettled state of medical opinion upon vaccination, and under the failing confidence of the public in its protecting efficacy, the members of that establishment, with no better reason than an apprehension that the inexperienced might make mistakes, and with no evidence whatever to justify their opinion, should pronounce the recurrence to the cow for fresh lymph as an undesirable measure; and yet, while deprecating this application to the original source of the disease, and while extolling the purity of the lymph used at the establishment, maintaining that it is a direct succession of that originally introduced by Dr. Jenner, the Report declares that the stores of the establishment have been occasionally recruited "with fresh matter from the cow!"

It is affirmed in this document, with the view of proving that cow-pox does not deteriorate, that "it is not in the nature of any other communicable virus

to degenerate and lose its influence." I would ask, is there any person long accustomed to vaccinate, who cannot testify from his own experience that there is a constant tendency in the vaccine disease to degenerate; that different constitutions so modify it, that, if care be not taken in the selection of the lymph for continued inoculations, it will become so weakened by passing through peculiar constitutions, as at length to be effete? The caution given in the Report is an implied admission of this fact.

Is it not also tolerably well ascertained, that, by a constant selection of the mildest cases for furnishing virus, inoculation for small-pox may be rendered comparatively safe? and that, at the time of the introduction of vaccination, this virulent morbid poison had been, in the opinion of some, so modified by successive inoculations, as to produce pustules for which the name of pearl-pox was proposed?

The want of care and accuracy in statistical detail in the Report, which has given an age of 19,000 years to the lymph employed at the establishment, has been commented on by others as well as my myself*, and, I have no doubt, will obtain much more notice when the document is perused by our continental neighbours.

Nor is it to the late Report alone that much may be objected. Considering the mass of information which the correspondence of the Board must have accumulated, it is impossible to read the Reports of former years without being struck with their meagreness. No statistics are given—no experiments detailed—no measures suggested either for the enforcement of vaccination, or the prohibition of small-pox inoculation. It does not, indeed, require much reflection to perceive that, however well intended the labours of that establishment may be, we must look to other quarters for that amount of observation, that statistical accuracy, and that general energy, which, in the present condition of the discovery of the immortal Jenner, the wants of the profession and the public demand.

It is much to be desired, that Government would allow the transmission of vaccine lymph from all quarters free of postage. Were this privilege extended

* See *Lancet*, March 9, 1839.

only to the Small-Pox Hospital, and the Royal Jennerian Institution, in London, instead of being confined to the National Vaccine Establishment, the provinces would probably be often supplied with more efficient virus.

To those who prefer the new lymph, I would suggest, as there is no chance of their being supplied with it from London, that when a fine vesicle presents itself, two or three dozen of ivory points be thoroughly charged, and preserved in a dry, well-corked phial for future use. From the experience I have had, I have no hesitation in saying, that the virus will thus retain its infecting properties for several weeks.

I cannot conclude these letters without acknowledging the valuable information I have derived from the extensive correspondence in which I have been engaged, as well as the gratification I have felt at the favourable manner in which my humble efforts to serve the cause of vaccination have been appreciated: my professional brethren may be assured that I will not neglect any future opportunity that may occur of procuring information upon this subject that may be either useful or interesting, and with thanks for the promptitude with which you have been pleased to insert my communications,

I remain, sir,
Your obedient servant,
J. B. ESTLIN.

Bristol, April 20th, 1839.

PARISIAN MEDICAL SKETCHES.

NO. I.—SŒURS DE LA CHARITÉ.

WHAT can I say good enough of you, ye good sisters of charity! Rather than write commonplace encomiums on virtue like yours, I would be silent altogether; yet how can I be silent who have been so often moved by your steady enthusiasm, and by the almost daily exhibition of some act of virtue, of which your whole lives are but the history! Ye unpaid nurses of sorrow and of sickness, whose only supports and comforters ye are—who, in the midst of “all the sad variety of woe,” when all medication fails, and life is fast ebbing away, still abide by the dying, and, when all is over, can go from the dead man’s

couch undismayed, to smile with a renewed interest on him who is recovering—ye who practise unheard-of self-denial—who never answer the coarse coarsely, or offend the peevish! I have seen ye for years, in many a trying strait, the peace-maker between the refractory patient and the not always reasonable doctor. Come into the ward St. Laurent with me. If you ask why this ward particularly, I will tell you. It is the most revolting ward at St. Louis, and St. Louis is the least enticing of hospitals. Internal disease may to the patient perhaps be even more awful in results or fears of results, but to the mere spectator disease can never manifest itself more shockingly than when its ravages are on the surface of the body. No, you will not enter that low-roofed, spattered, and bemired apartment, of which the very look from the doorway terrifies. Why should you breathe that rank, close air, heavy with the smell of sores, of salves, and of sulphur? Why should you penetrate those foul recesses, and pass from bed to bed amidst yon crowd of half-naked ruffians, steeped in abominations of all sorts—youths who speak but to imprecate, and *blasés* old villains, offensive to every sense? To witness, but for once, such a mixture of fierceness and of filth, of misery united to mischief, you will not, even for curiosity’s sake, pass under those low arches; and you are right: mere curiosity must turn away her head, sick, and unable to proceed. Yet, in the midst of all this, which you see from the door that I have opened, behold, and with reverence, one of those modest “*sœurs*” in her clean white and black head-gear, ministering with her soft womanly hands to that unsightly crew, or quietly knitting or sewing—for she never permits herself to be unemployed. “*Aussi, ce n’est pas par intérêt que nous le faisons,*” said she to me the other day, smiling in sweet complacency at my unreserved communication of my feelings; which words, I remember, were scarcely out of her mouth, when a refractory young *galeux*, who had been repeatedly admonished, that, if he did not conduct himself better, he would be sent away from the hospital, was summoned to appear before the physician; having listened with impatience to whose reprimand, the monster replied, with great vehemence, and with knit vindictive brow, “*C’est la haine*

qui fait que la sœur s'est plain de moi !” The sister said nothing, but bent her eyes on the ground; for ourselves, we could, even at the chance of catching his disorder, have felled the young recreant with a blow; but the physician’s words settled, in a most eloquent manner, this vindictive attack. “Silence, sirrah! and for shame.” “Ici on ne reconnaît que bienveillance et miséricorde!”—out with his name—“rayez son nom!—exeat.” Dr. Cazenove was that physician.

Nor are the amiable sœurs’ duties confined to such as, it is to be hoped, generally appreciate their inestimable support! What though they have never been mothers—go to the Hôpital Jesus, filled with sick babies and scrofulous childhood, and say there if it be possible for even maternal *σταγην* to be more adequately represented. The sick child is a heavy burthen to the fondest parents. We love to play with our brats, which requires them to be well; and more than playthings, till there be some exchange of mind—some companionship—they cannot be. Instinct attaches, and pride is gratified where grace or comeliness qualifies its object; but the sœur looks throughout upon these poor children in a widely different light. With her these hapless little creatures are sacred deposits, of whose souls and bodies alike she considers herself to have become the temporary guardian; and whether it be to flourish on earth, or to be forthwith transplanted into heaven, her tender culture of the young plant is still the same. Any morning between nine and ten, if you ask for the “salle des teigneux,” you will find, as I have done, a semicircle of little urchins from seven years up to fourteen, all in their white night-caps, and all but one, who is the biggest, sitting under her presidency to pick lint: he is standing, to read aloud for the benefit of the younger community, while the kind “sister of charity” sits by correcting his blunders; and so intent are the little folk at once on their rag picking and the story, that you may generally approach quite close to them before you are perceived: then, perhaps, an immediate stir takes place; the reader puts his book down disconcertedly, and his kind prompter rises to meet you. Do not now be afraid of putting her out, or scrupulous not to ask her too many questions. The only

compliment you can pay a sœur is to take an interest in what most interests her—doing good. If, in shewing you her young charges, she does not use periphrasis—if she speak the naked truth sometimes too plainly for your habits—remember the sœur is no fine lady; hers is only the refinement of mind, which religion can alone confer; she knows nothing of conventional phrases. If she conduct you to a poor little thing, frightfully emaciated, whose tense abdomen is blown out like a balloon, and whose attenuated members look rather like a roll of Herculean papyrus than human skin; and if she quietly state, in his bearing, that he has been given up and will not live many days, be not shocked without necessity, for the little unconscious creature has none of your fears of dying; he hears the announcement without anxiety or even interest, and asks “sa bonne sœur,” with a ghastly effort at a smile, to give him a little drink!—But I am becoming garrulous, and had nearly forgotten, in the society of the good sœurs, that I had a reader, perhaps a fastidious one.

NO. II.—DOCTORS.

If it be true that troopers are extraordinary liars, M.— would deserve to be their captain. When he chances to be in a good lying humour, it is extremely difficult to keep pace with him. His romances are as long as Scudery’s, and much more diverting. I never knew a man so at home in the absurd or the impossible as M.—. I have seen him at his hospital at 9 A.M., and he has already seen a hundred patients and been three times round Paris.

Some men are great talkers upon one favourite subject,— he is equally voluble upon all. I have heard him, in the brief space of ten minutes, touch upon literature and lepra, and descant on politics and prurigo. He is addicted—

“To raising questions dark and nice,
To solve ’em after in a trice;
As if Philosophy had catch’d
The itch, on purpose to be scratch’d.”

“Now, gentlemen,” he would say, when the visit was over, and he was in the act of untying his apron-strings, “now what would you do in such a case as the following?”—and then he would give one in which a conjuror’s, not a doctor’s, services seemed

wanted: such a case, however, had only just happened to him, and was already doing well. The patient was generally an Englishman, "grand bel homme (fort distingué du reste)," whose name he was not permitted to mention. Of what he told us while he was washing his hands and we were looking for our hats, the following is a *souvenir*:—"Econtez!"—we turned our heads; "I am going to put a case to you—or, stay, I may as well tell you the case, as it occurred to me some weeks ago. An Englishman had an angry discussion with his wife; he determined, therefore, to commit suicide, and divided his throat from ear to ear with a razor. I was called in. I never saw any thing so frightful in my life: blood was pouring from an immense gaping wound all round the neck; besides which he had lost a *mer de sang* before I saw him! Having satisfied myself as to the case of this rash act, I requested my patient (as I saw no time could be lost) to let me stay the bleeding. 'Sir,' replied the man (whose throat was cut from ear to ear), 'I am weary of life (*le tedium vitæ* des Anglais)—let me die.' But having lectured him upon the impropriety of his conduct, and having represented to him 'sa position, ses devoirs,' &c. he at length consented to my saving him; adding, however, that the attempt was quite futile—that I might spare myself the useless trouble—that he had cut his throat too deep, and that nothing could now succeed." The philosophy of Seneca in the bath was a joke to the *sang froid* of our distinguished countryman. "What did you do, sir?" "Il n'y avait rien de plus simple. I contented myself, having drawn down his head, with keeping the divided surfaces together by a few simple stitches; requesting him to repose, and not upon any account to turn his head. He complied with my request, and at the end of five days I had the pleasure of meeting him on foot, on the Boulevard Italien." "The treatment was very simple," said the youthful clerk. "Yes, when you know it," said the other: "but, gentlemen, allow me to put to you a less serious case, and see how you could extricate yourselves under the following circumstances:—Suppose yourselves, any of you, summoned to a great lady, living in a great house at the fashionable quarter of

Paris. She is extremely sensitive and impressionable; she has snapt a needle in her finger, which lies at some depth from the surface, between it and the nail. I know what you will say—'I would get a pair of English tweezers,' *bien fines*, 'and try to draw it out; or if too low, I would make a little incision, and then use the tweezers.' Ah, no! at least that is not what I did. Guess again. Come, I'll tell you what you would have done on reflection, and it is just what I did: I ordered a basin of warm water, and made the lady soak her hand in it till the nail began to soften; then I took a very fine pen-knife, and paring away layer after layer of the horn, it became at last as thin as silver paper. Then I made an easy aperture through its side, right over the needle, which I now drew out without the least difficulty, and without giving the lady any pain, which was what I particularly desired to avoid. Tenez, voilà encore un cas lequel s'est présenté depuis peu." This was the case of a fish-hook which had penetrated deeply into the hand;—but I did not stay to hear whether it was of English or Irish manufacture, of the Limerick or Kirby bend; nor whether nor how it was extracted.

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abrégé."—D'ALEMBERT.

Lectures on Diseases of the Eye. By JOHN MORGAN, F.L.S. 8vo. pp. 221.

THE object of this work is to describe the more common and important diseases of the eye, with their treatment; and to illustrate the analogy between these maladies and those of other parts of the body.

Mr. Morgan first treats of diseases of the conjunctiva, under which head we find catarrhal ophthalmia; aphthous, or pustular inflammation of the conjunctiva; variolous ophthalmia; purulent ophthalmia in infants; purulent ophthalmia in adults; strumous inflammation of the conjunctiva; pterygium; staphyloma racemosum; chemosis of the conjunctiva; and granular conjunctiva.

The second division is on diseases of the cornea, and contains inflammation of the cornea; nebulous cornea; ulcera-

tion of the cornea; conical cornea; abscess of the cornea; and staphyloma of the cornea. We next come to morbid affections of the iris, under which we find prolapsus of the iris; common inflammation of the iris, or iritis syphilitic iritis; and arthritic iritis.

Under diseases of the sclerotic are to be found inflammation of the sclerotic; staphyloma of the sclerotic; choroiditis; hydrophthalmia; atrophica oculi; and synechisis [synechysis].

The next division is on diseases of the retina, under which we find inflammation of the retina, and paralysis of the retina, or amaurosis.

Next comes a chapter on cataract; and then one on malignant diseases of the eye, namely, melanosis and fungus hematodes, with an account of the operation for removing the globe.

There is then a chapter on operations, containing those for cataract, by extraction, depression, and solution; with the one for forming an artificial pupil. The work concludes with an account of entropion, ectropion, and the morbid affections of the lacrymal conduits.

The following observations will be useful to many practitioners as well as students:—

“It may appear absurd to suppose that any medical man in his senses would throw a stimulating injection into the eye, as a preparatory step to separating the lids, and obtaining in that way a view of the inflamed globe. Yet many are producing now and then the very same effect as that which would result from such a proceeding by different means.

This effect is occasioned by the manner in which many a novice is in the habit of opening an inflamed eye. I speak of what I am not unfrequently witnessing in my practice; and as I know how few of you are acquainted with the proper mode of examining an inflamed eye, I shall take this opportunity of giving you a few directions upon the subject. There are three different ways of opening the eyelids, represented in Plate 18, figs. 1, 2, 3; and although each of the diagrams is a caricature, I do not hesitate to say that many who see them would, if asked, mistake the right way for the wrong, or *vice versa*.

The usual mode in which a bungler makes the attempt is represented in fig.

1. Each thumb is placed on the margin of the tarsal cartilages—pressure is made down upon the globe—the orbicular contracts powerfully from sympathy—and thus the conjunctiva of the lids and of the globe are rubbed together as the lids are slid over the anterior part of the latter. The natural consequence of this mode of proceeding must be obvious; when two inflamed membranes are rubbed and pressed together, of course the diseased action will be increased; and, consequently, when a successful effort has enabled the operator to draw asunder the lids in the manner I have now described, it is found that the vascularity of the part is very greatly increased from irritation produced by previous pressure and friction.

This, then, is the most common mode of opening an inflamed eye improperly, and the consequences are always as I have stated.

The next diagram (fig. 2) represents a less common, though at the same time a far more injurious mode of making the examination. It consists in the process of insinuating elongated finger nails between the lid and the globe, and thus clawing the inflamed surfaces asunder. That such an operation must necessarily tend not only to produce a temporary excitement, but also a permanent increase of inflammatory action in the part, will not be doubted. Yet I know from experience that this operation is practised too frequently to be passed over in silence upon the present occasion. Look at these two diagrams, and see whether before you are twelve months older you do not observe an illustration of the error here represented.

Having now shown you the consequences of an unskilful attempt to open an inflamed and swollen eye, I will next describe to you the proper mode of performing this very simple operation. Your object will be to *separate* the inflamed surfaces of the conjunctiva of the lids and globe at the time you are opening the eye, and to avoid making any pressure upon the part; this will be easily accomplished, unless excessive tumefaction of that part be an obstacle, by gently drawing the integuments of the lower lid downwards towards the cheek with the point of the fore-finger of one hand,

and with the thumb or fore-finger of the other, drawing the skin covering the upper lid upwards towards the supra-orbitor ridge: the diagram (fig. 3) represents what I have described. Be careful in opening an eye to avoid throwing a strong light on the part, as it sometimes renders the operation difficult, from the spasmodic contraction of the orbicularis palpebrarum, and in cases where the retina has been rendered morbidly irritable, a temporary increase of vascularity will generally be the consequence." (pp. 24—6).

On the whole, these lectures are sensible and judicious, and though chiefly intended for the use of Mr. Morgan's pupils, will be consulted by other persons also. The plates, of which there are eighteen, drawn on zinc by Canton, add much to the value of the work.

—
Wiesbaden als heilsemer Aufenthaltsort für Schwache und Kranke aus dem Norden Europa's, und als Kurort für jede Jahreszeit, mit besonderer Bezugnahme auf die Zulässigkeit des Gebrauchs von Winterkuren, dargestellt. Von GUSTAV. HEINRICH RICHTER, Doctor der Medicin und Chirurgie, praktischem Arzte und Wundarzte zu Wiesbaden, &c. Elberfeld, 1839.

Wiesbaden considered as a Residence for Invalids and Patients from the North of Europe, and as a Watering-place for every Season of the Year, &c. By G. H. RICHTER, M.D. Elberfeld, 1839. 8vo. pp. 94.

THIS little work is divided into four chapters. In the first one Dr. Richter examines the claims of Pau, Montpellier, Aix, Marseilles, Nice, Genoa, Florence, Rome, Naples, and other celebrated spots, to be considered as places of refuge for invalids, especially pulmonary ones; and shews that no one of these towns is free from some capital defect. In this division of his book our author chiefly follows Sir James Clark. In the second chapter he asserts that Wiesbaden is an excellent asylum for patients in winter and spring, from the extreme mildness of the temperature. At one o'clock in a March afternoon, the thermometer in the shade sometimes stands at from $63\frac{1}{2}^{\circ}$ to 68° of Fahren-

heit; while in April it has several times risen to $65\frac{3}{4}^{\circ}$, and up to 77° ; in May, from $83\frac{1}{4}^{\circ}$ up to $90\frac{1}{2}^{\circ}$. In summer it rises to 95° or even to $99\frac{1}{2}^{\circ}$ —a painful temperature, which occurs, however, rather in the old town, near the hot springs, than among the new buildings.

In September and October the sky is often beautifully clear, with the thermometer ranging from $65\frac{3}{4}^{\circ}$ to $72\frac{1}{2}^{\circ}$, and even 86° , of Fahrenheit; so that many patients are induced to prolong their stay, and even look out for a winter residence. Among the southern trees which grow around Wiesbaden, are to be found the *Amygdalus communis*, *Platanus occidentalis*, *Liriodendron tulipifera*, *Bignonia Catalpa*, and *Ficus Carica*; while the walnut and the Spanish chesnut form whole alleys and small woods. All these trees, however, are pretty common, we believe, in the south of England, without even going to Devonshire for examples; and in that favoured county the myrtle and some other plants stand the winter, which do not appear in the Wiesbaden list.

Among the foreign plants which have become naturalized, and now grow wild, are to be found the *Angelica archangelica*, *Arenaria saxatilis*, *Adonis vernalis*, *Alyssum campestre*, *Draba muralis*, *Gentiana asclepiadea* and *bavarica*, *Ligusticum levisticum*, *Nymphaea minima*, *Stellaria nemorum*, *Valeriana Phu*, &c. &c.

The oldest persons in Wiesbaden, many of whom are upwards of 80, and some have attained the age of 90, do not recollect the prevalence of any destructive disease. There are no endemics, and the ordinary epidemics, such as measles and scarlatina, are neither malignant in type, nor long in duration. Inflammatory diseases are seldom acute, and intermittent fevers are seen at Wiesbaden only when they have been brought there. Many a Dutchman owes the final cure of his ague (which is an endemic distemper in his country) to the climate of Wiesbaden.

The amusements of the *Kursaal*, or pump-room, during the summer, are music and dancing, and, unfortunately, gaming also; which, as an English writer observes, in his "Wiesbaden recommended to the Gouty and Rheumatic," does not mix well in the waters.

The theatre is open four times a week during the season, and twice a week in the winter.

There are two reading-rooms, where German, Dutch, French, and English newspapers are to be found, "saving only the leading journals supporting the government of her Majesty the Queen of England. The *Morning Chronicle* is prohibited." — (Wiesbaden recommended, &c. p. 15.)

The third and fourth chapters we must dismiss very briefly.

Patients who come to Wiesbaden in the spring, besides the warm baths, can have the advantage of the fresh juices of plants, which form, says our author, what is called the spring course; being added, we suppose, to the baths. Among the patients for whom bathing at this season is peculiarly advantageous, are those for whom we may anticipate an after-treatment will be requisite—such as a course of chalybeate water, or river or sea-bathing, or a *Traubenkur* (course of grapes) — *i. e.* a diet restricted to grapes and bread.

A great advantage at Wiesbaden, as well as many other German watering-places, is, that the baths are in the hotels, so that the patient is scarcely liable to take cold in his transit to and from.

On the whole, Dr. Richter's book will afford very useful information both to physicians and invalids, especially by the discrimination he shews in setting forth the classes of disease for which the various seasons of the year are severally most fit; and though the medium through which he views every thing is tinged of too deep a rose-colour, yet this excess of good humour must be excused in a physician resident on the spot; it does not go against the grain, says Aristotle, to praise the Athenians at Athens.

If we might venture to give a hint to Dr. Richter, we could direct his attention to that passage in the pamphlet of the gouty layman, where he complains that the Wiesbaden physicians do not speak English; British fees are no bad things, a guinea being equal to about 12 florins and 36 kreutzers of Nassau money.

MEDICAL GAZETTE.

"Licet omnibus, licet etiam nihl, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

EXPERIMENTS ON LIVING ANIMALS.

OUR readers will remember that some time since we alluded to this subject, with a view to shew how far it was justifiable for any member of our profession to inflict pain upon animals, and under what circumstances he might be deemed to have incurred moral guilt by this method of pursuing the investigation of his science. Since that time, a member of the Society for the Prevention of Cruelty to Animals has offered a prize of £100 for the best treatise on the subject; and amongst the works sent in in competition, two (at least) have since been published—one by the successful candidate, a Dr. Styles—the other by the well-known and respected veterinarian, Mr. Youatt. With these works before us, we are induced again to recur to the subject, that we may endeavour to clear the character of our profession from much of the obloquy which has been cast upon it, and to free it from at least that part of the general odium which it in no degree deserves.

Nothing could more clearly shew than the simultaneous appearance of these works, how vague are the principles on which the accusation of *cruelty* is charged against men. For what is cruelty? Dr. Styles, who seems a man of good but unrestrained feeling, says (p. 22)—"Cruelty, whether it be for gain or amusement, for the gratification of appetite, the promotion of science, or even the sustenance of human life, is the UNNECESSARY infliction of pain." But this is just no definition at all; for the word *unnecessary*, as here used, is itself entirely indefinite. If he means

that no pain is to be inflicted for any of the good purposes enumerated, except that which is *absolutely necessary*, he would confine all men to the food that they could obtain from the larger animals and from vegetables, and many to vegetables alone, because animal food, or at least that food which incurs the slaughter of many and small animals, is not *absolutely necessary* to the sustenance of human life. The slaughter of one ox, for example, would afford as abundant and wholesome food for 100 men as the slaughter of 100 head of game or small poultry; therefore, under this interpretation of cruelty, that food only could justifiably be eaten, for the supply of which the smallest possible number of lives is sacrificed; and, except perhaps, for some invalids, the only animals it would be fair to slaughter in this country would be the ox and horse. Of course, the warmest members of the Society do not hold such a creed as this; but it is clear that this is what Dr. Styles' and their definition fairly and directly leads to.

If, on the other hand, *necessary* means not that which is absolutely indispensable, its meaning must be decided by the sense in which, on this subject, it is commonly received: in other words, *necessary* must here be taken as synonymous with *justifiable*, and its precise meaning will vary with the varying feelings and opinions of the public. In this view Mr. Youatt writes of cruelty, and regards as justifiable many practices (as hunting, fishing, and shooting) on which Dr. Styles pours some of his loudest anathemas. Such is the uncertainty of the very foundation and subject of all arguments on cruelty. In the abstract definition of one party, the prohibition of cruelty to animals would incur the loss of a vast while the majority of the articles of our

food more loose meaning of the other party would permit many practices which the feelings of good men would regard with disgust. It is not our province to decide the meaning of the word, or to enumerate what practices are or are not necessary or justifiable; but it will be sufficient if we can shew that those who, *under certain restrictions*, perform experiments on living animals, are as fully and as fairly innocent of cruelty as many of those who are most distinguished for their humanity; and we will endeavour to prove this in any sense in which the word can be fairly understood.

The whole tone of Mr. Youatt's book indicated the kindest feelings, and the most earnest anxiety, by every fair means, to alleviate the sufferings of every living creature; and his constant and active exertions for their good, claim for him the just title of their best benefactor. Yet he, who might be regarded as a model of humanity, not only permits, but sanctions by his presence, and encourages with the heartiest and most glowing praises, the practice of hunting. Now it is in vain to deny that this pursuit is the cause of the infliction of severe pain and death to animals, for the amusement of men. It is said, "we have a right to the flesh of the inferior animals as food;" hares are food, and therefore we hunt the hares and kill them. And all this might be true if the men who hunted wanted the hares, or ate them when caught; but the very reverse is the case: one hare is no sooner killed than the hunters rush away in pursuit of another, and leave the victim. Nay, it is thought almost essential to the good character of a sportsman, that he should *not* eat the game which he has himself taken. When, therefore, his privilege of hunting is questioned, he can have no right to

shield himself behind the necessity of killing animals for food, because those who hunt neither want nor eat the game; nor if they did, would it be necessary to engage a field of fifty or more horsemen, and a pack of dogs, to take it.

But it is useless to argue such a point: however special pleading may obscure or pervert it, the fact, which every honest hunter will allow, is, that he pursues his game for the pleasure which its pursuit affords him, and that for his pleasure he does not hesitate to put an animal to pain or death. And far be it from us to say that such pursuits are unjustifiable, or even degrading, to those who follow them; only let their end be distinctly understood—that it is for the immediate gratification of men, and not to supply their bodily or pecuniary wants.

“As for the fox, he is legitimate prey,” says Mr. Youatt; “he is a felon by nature.” True; but it is not for that reason he is hunted, but rather for his speed and good wind, his cunning and his courage: but for these, men would have left him to boys to be exterminated. Indeed, but for hunting, foxes would have been put an end to long ago, for they now exist only where they are wanted for sport; and in a neighbourhood where no hounds are kept, the villages can soon rid themselves of these “felons by nature.” In the same way badgers are altogether exterminated, where they are not wanted for baiting; and thus, if an argument were needed to justify a humane man in these pursuits, it might be shewn that the best mode of increasing the total amount of life, and thereby of enjoyment, to animals, would be to make them, when full grown, the object of men’s pursuit, and to prevent them from being destroyed while young. We recommend this, though it may be rather sophistical, to the notice of humane

hunters. But for hunting, many animals would not be wanted, and they would therefore be soon exterminated; *ergo*, hunting is in the end the most humane proceeding towards the animals themselves, whose lives and generations are prolonged for its sake. But to return:—In this and in every other case of the kind, the main motive that induces men to hunt is the pleasure that it gives them—a pleasure which nearly all men enjoy; as Mr. Youatt says, “the mild and the sedate, the benevolent and the reckless, can scarcely find language sufficiently expressive to tell of the pleasure which they feel.”

Man’s pleasure, then, is a sufficient motive for permitting and encouraging the infliction of pain and death to animals. A thousand instances could be quoted in which the kindest and most benevolent men have practically admitted this, in their love for the turf, the field, the angle, and the gun; and the man must be mentally or bodily deficient who cannot enjoy any of these pursuits, or who is insensible to the invigorating delights which they afford. On the same ground, then, experiments on living animals may, *under certain restrictions*, be as fairly justified. Will any one deny that there is intense pleasure in the pursuit and possession of truth? What though the facts ascertained by pain are not capable at once of being turned to practical good; is not truth for its own sake desirable? Compare the two pursuits: the justified and sanctioned hunter or angler inflicts pain and death for his own most intense pleasure; his pleasure gratified, the sport is left, and all is forgotten; no benefit results to himself or to his fellow men. The vivisector for his most intense pleasure also inflicts pain and death; but the *truth*, which is the object of his sport, is permanent, and affords an equal pleasure, and per-

haps vital advantages to thousands of his fellow-men. And—for the pursuits themselves—which is most worthy of the rational and intellectual men—the pursuit of truth, or that of foxes? Mr. Youatt adds to his grounds for justifying hunting, that the horses and dogs themselves delight in it. “There never was a biped who entered so thoroughly, heart and soul, into the joys of the chase, as does the horse;” and is it not enough to shew that it is not the most worthy pursuit of men, that it should be the chief pleasure of horses and dogs? The most exalted men are those in whom the qualities which they possess in common with animals are least prominent, and best restrained; and the object which offers equal pleasure to men and brutes can therefore be scarcely regarded as a worthy aim for the exertions of the former.

It is clear, then, that if with ninety-nine hundredths of the world we admit that it is justifiable to obtain a great pleasure by the infliction of some pain on an inferior animal, experiments on living animals may, on this ground, be as justifiable as hunting, shooting, or fishing, when not followed for the maintenance or necessary comforts of life. In the same way we might show that they are not less justifiable than the pursuit of most branches of natural history—ornithology, entomology, conchology, and many more; all followed with the infliction of pain and death to thousands, and their only object the gratification of mankind in the possession of truth, and their occasional benefit by the discovery of useful materials or principles. In short, if we look around us, there is scarcely a pleasure, a luxury, or even such a comfort as we call *necessary*, that is obtained without the suffering of our fellow-creatures. At present we do not

intend to prove more, for it will be sufficient to shew that so large a majority of the world have no right to raise a clamour against the pursuits of men of science, or to charge them with crimes of which they are themselves guilty. We would not accuse either class of cruelty; each, perhaps, often overlooks the means in contemplating the value of the end for which he strives, and there can be but few in either who love their pursuit for the sake of the means rather than of its object. There may be vivisectioners who enjoy the infliction of pain, or thoughtlessly allow more than is necessary for the success of their experiment; but they are not more numerous than those who enjoy a long and destructive chase, and a *killing* pace, as it is called; or who feel exquisite pleasure in the very writhings—the *playings*, as they term them—of the hooked victim of their deception.

We will now only beg any of our readers who may imagine that we would sanction the indiscriminate employment of vivisection, or even that amount of it which is at present practised, to suspend their judgment till in a future article we point out some of the restrictions the observation of which makes it, in our opinion, justifiable. We say *justifiable* only, because as yet we have placed vivisection only on the level of what are commonly called desirable, noble, and manly pursuits; but we think that we can prove that it has had, in some cases, a claim to a less equivocal title, and that, if not *absolutely necessary*, it has conduced as much to the good of mankind in the treatment of diseases as there has resulted of benefit by the constant use of many articles of animal food, which are acquired only with the infliction of the same pain and death.

WESTMINSTER MEDICAL SOCIETY,

Saturday, April 20, 1839.

W. D. CHOWNE, ESQ. M.D. PRESIDENT.

Financial Measures.—*Mesmerism.*—*Carcinoma of the Stomach.*—*Liquid Carbonate of Magnesia.*—*Ossification of the Aortic Valves.*—*Influence of the Mind on the Course of Disease.*

THE evenings of the 6th and 13th of April were almost entirely consumed in discussions relating to the financial difficulties of the Society. It was finally determined by a small majority, and passed into a law, that all the actual members of the Society should pay an annual rent of half-a-guinea each, on pain of being excluded from all share in the government of the Society; and that all future members should pay the same rent after the expiration of two years from the date of their admission as members. The present admission-fee of one guinea was to be required as formerly.

The only matter relating to science that was introduced during these two evenings was a detail of experiments performed in *lady's school*, by a Mesmerical practitioner. The statements might be considered as perfectly ridiculous, and laughed at accordingly, were it not that indignation is naturally excited at the gross impropriety of tampering with the feelings and principles of helpless children.

This evening Dr. Sayer placed on the table the abdominal viscera of a woman, who, after suffering for eight years with carcinoma of the stomach, died in great suffering. The whole of this viscus was more or less affected. The cardiac orifice, however, was the chief seat of disease. The interior of the stomach was one continuous ulcer. The duodenum was comparatively unaffected, which Dr. Sayer thought remarkable. There were other portions of the alimentary canal affected with the carcinomatous mischief, and several constrictions had taken place in consequence: one especially in the ascending colon, a little above the cæcum, was remarkably strait, and must have very much obstructed the passage of the feculent matter.

Sir James Murray was now introduced by Mr. Costello, and exhibited to the society a bottle of liquid carbonate of magnesia. This fluid was perfectly transparent and colourless: when tasted, it presented the sapid qualities of the ordinary salt. It was dissolved under great pressure of carbonic acid, in a vessel con-

structed in the same manner as that in which is employed in solidifying carbonic acid gas. The solution seems permanent, and is not soon acted upon by exposure to the atmosphere. The magnesia will be precipitated if a heat of 212° be applied. Each ounce of the liquid contains 15 grains of the solid carbonate of magnesia; but this salt, according to Sir James Murray, is, whilst in solution, three times as active as when solid; a tea-spoonful of it is a dose for a child, and a table-spoonful for an adult. The liquid is capable of being employed for making infusions at a temperature below the boiling point.

Mr. Gregory Smith exhibited a heart which he had taken from an elderly woman, who was cook in a large family. On the day of her death, which took place suddenly, she cooked a dinner for fourteen people, and was for a long period previously actively employed. She had occasionally fits of dyspnoea; the heart was considerably enlarged. The parietes of the left ventricle were an inch and a half thick. The sigmoid valves of the aorta were so incrustated with amorphous ossific matter, that the passage was reduced to the size of a crow-quill; and it appeared surprising how the blood could have found its way into the general system. The coronary arteries were also very much ossified, and the aorta and pulmonary artery were remarkably thin. The disease is supposed to have existed eight months.

Mr. Forbes Winslow next read the following paper on the—

INFLUENCE OF THE MIND ON DISEASE.

The science of medicine, and the science of morals and metaphysics, are more closely allied than medical men are disposed to admit. To treat disease successfully—to be able to grapple with the many ills that flesh is heir to—requires, on the part of the practitioner, a more intimate acquaintance with our moral and mental constitution than, *à priori*, we should be inclined to suppose. He who considers the practice of medicine to consist only in the administration of drugs, entertains but a low estimate of the nature and difficulty of his profession. "To be a discerning physician, it is necessary to be a tolerable metaphysician:" so said Dr. Cullen. It was not, however, his intention to recommend that species of reasoning which confounds the mind without enlightening it, and which, like an *ignis fatuus*, dazzles only to lead us from the truth. To the medical man we can conceive no preliminary studies more productive of advantage than those which tend to call into exer-

tion the latent principle of thoughts, and to accustom the mind to habits of close, rigid, and accurate observation. The science of mind, when properly investigated, teaches us the laws of our mental frame—shews us the origin of our various modes and habits of thought and feeling—how they operate upon one another, and how they are cultivated and repressed: it disciplines us in the art of induction, and guards us against the many sources of fallacy in the practice of making inferences: it gives precision and accuracy to our investigations, by instructing us in the nicer discriminations of truth and falsehood.

The passions are to be considered, in a medical point of view, as a part of our constitution. They stimulate or depress the mind, as food and drink do the body. Employed occasionally, and in moderation, both may be of use to us, and are given to us by nature for this purpose; but when urged to excess, the system is thrown off its healthy balance, and disease is the result.

It is curious to notice the reciprocity of action existing between different mental conditions and affections of particular organs. Thus, the passion of fear, when excited, has a particular influence on the action of the heart; and when a disease of the heart takes place, independently of any mental agitation, the passion of fear is called into exercise. Anger affects the liver, and confines the bowels, and frequently causes jaundice; and in hepatic and intestinal disease how irritable the temper is! So sensible was Dryden of the effect of a loaded condition of the bowels on the mind, that he was accustomed to prepare for a course of study by a course of medicine. "When I have a grand design," he observes, "I even take physic and let blood; for when you would have swiftness of thought and fiery flights of fancy, you must purge the belly." One of the most famous disputants of antiquity always dosed himself with white hellebore preparatory to his refuting the dogmas of the Stoics. Voltaire appears also to have been aware of the connexion alluded to, for he says—"If you have any favour to ask of a king's minister, or a minister's secretary, or mistress, take an opportunity of approaching them after they have had a comfortable evacuation from the bowels." Hope, and the anticipation of pleasure, affects the respiration; and how often do we see patients in the last stage of pulmonary disease entertaining a sanguine expectation of recovery even to the very last!

The passions may be divided into those that excite the powers of the vital system, or rouse the faculties into action, or such as depress and debilitate them.

In diseases in which debility is the pro-

minent symptom, those affections of the mind which rouse the torpid condition of the bodily frame must be called into action. Lord Anson says, in speaking of the ravages which the scurvy made among the men under his command, that "whatever discouraged the seamen, or damped their hopes, never failed to add new vigour to the distemper; for it usually killed those who were in the last stages of it, and confined those to their hammocks who before were capable of some kind of duty."

Again, at the siege of Breda, in 1625, we have an interesting example of the good effects of the exhilarating passions. That city had suffered from the effects of a long siege, and the inhabitants had experienced the miseries of fatigue, bad provisions, and distress of mind; the scurvy had also carried off large numbers. The place was on the eve of being surrendered to the enemy, when the Prince of Orange introduced letters to the men promising them speedy assistance. A medicine, which was represented to be of the greatest efficacy and of high price, was also forwarded to the sick in the garrison. Three small phials were given to each physician. The effects of this deceit were truly astonishing. It was publicly given out, that three or four drops were sufficient to impart a healing virtue to a gallon of liquor. Then invalids flocked in crowds to the physicians. Many who had not moved their limbs for a month before, were seen walking the streets with their limbs sound, straight, and whole. Dr. Sind, who relates the particulars of this circumstance, says it was told him by an eye-witness, an author of great candour and veracity, who wrote down every day the state of his patients, and who seemed to be more surprised with their unexpected recovery than he probably would have been had he been better acquainted with the nature of this surprising malady.

A thousand years before the Christian era, there were at the two extremities of Egypt temples devoted to Saturn, to which those labouring under hypochondria resorted in quest of relief. Some cunning priests, profiting by the credulity of these hypochondriacs, associated with the pretended miracles of their powerless divinities and their barren mysteries, natural means, by which they always solaced their patients, and succeeded often in curing them by amusing the mind, and inspiring confidence and hope. These means were diversions and recreative exercises, to which the invalid was religiously subjected. Voluptuous paintings and seducing images were exposed to their view. Agreeable songs and melodious sounds perpetually charmed their ears. Gardens of flowers and ornamented groves furnished delight.

ful walks and delicious perfumes. Every moment was consecrated to some diverting scene and amusement, which had a most beneficial influence on the diseased mind—interrupted the train of melancholy thought—dissipated sorrow—and wrought the most salutary change in the health of the body, by acting on it through the agency of the mind. The Egyptian physicians advised their patients to repair to those famous temples, as the faculty of the present day suggest a trip to a fashionable Spa.

In many cases when the nervous system is in a debilitated and depressed condition, it will be necessary to endeavour to rouse the mental and physical energies of the patient, to prevent him from sinking under the influence of the disease. In the army, it is proverbial that the time of fatigue and danger is not the time of disease. It is in the inactive and listless months of a campaign that crowds of patients pass to the hospitals. In both these cases it is active exercise giving strength to the brain, and, through it, healthy vigour to the body, which produces the effect. How often do we see the absence of all fear invigorate the system, and render it less susceptible to the action of contagion! Thucydides, speaking of the plague of Athens, says that the most affecting circumstances were the dejection of mind which attended the first attack; for the mind sinking at once into despair, they gave themselves up without a struggle. Whenever Rome was threatened with a pestilence, the authorities marched with great pomp and in solemn procession to the temple dedicated to the god Febris, when a nail was driven into the temple, which was supposed to appease the angry deity. This inspired the people with confidence, and rendered the epidemic, if it made its appearance, less fatal and general. It is only on this principle that we can account for the wonderful efficacy which some charms were supposed to have in preserving the body from the influence of contagion.

From these facts, it will appear evident how imperative it is on the part of the profession, during the existence of any pestilential disease, to do their utmost to prevent the public mind from being unnecessarily depressed by fear and apprehension. It may be a point worthy of our consideration, whether in epidemic diseases admitted to be contagious it would not be politic to keep that fact as much as possible from the public: it is certainly our duty to allay public apprehension, and to invigorate the body, by exciting hope, confidence, and fearlessness, in those exposed to the disease.

Much of our success in practice will de-

pend upon our placing about the patient persons of cheerful and lively dispositions. How often have our best directed efforts proved abortive, owing to the circumstance of the invalid's mind being depressed by those in attendance, who ought to do their utmost to encourage hope and to inspire confidence in the means used to promote recovery. The following is a case in point:—I was some years ago attending a lady labouring under a uterine affection, attended by great mental dejection. She was nursed by a female relative, who paid every attention to her that kindness and humanity could suggest. The patient, however, appeared to get no better. An idea had taken possession of her imagination that she was going to die, and this notion was encouraged by the female who was in constant attendance at the bedside. The nurse was naturally of a melancholy cast of mind. Whenever she approached the invalid, she would, with uplifted hands, pour forth bitter lamentations: she groaned, sighed, and prayed, until the poor girl was induced to believe not only that she was really at death's door, but that she was destined to be eternally lost. Her mind had been thus powerfully acted upon for some time unknown to me, and she was daily sinking under its influence. I happened to visit her one afternoon when the kind but inconsiderate nurse was, as she thought, administering to the patient spiritual consolation.

I saw in a glance the cause of all the mischief against which I had vainly been endeavouring to contend. I insisted upon having another nurse of a cheerful turn of mind to attend the patient. With difficulty my wish was accomplished. Need I say what was the result? An immediate improvement took place; and in the course of a few days the patient was able to leave her chamber, where she had been confined for some weeks, and where she would have died, had the nurse of the sorrowful countenance been allowed, by her injudicious conduct, to prostrate those mental energies which it was her duty to have stimulated, by holding out every encouragement and hope to the patient.

In the moral treatment of derangement of mind much good is to be effected, if the degree, character, and peculiarities of the malady be taken into calculation. I think it is a great error to suppose that all lunatics are inaccessible to reason, and insensible to the ordinary feelings of humanity. In the early stages of insanity it may be possible to reason a person out of his delusions; but in the more advanced stage, the patient's morbid ideas, affections, or inclinations, ought never to be opposed. The physician ought carefully

to watch for the first dawns of convalescence, for it is at this period that he can bring effectually into operation his moral agents. The first glimmer of returning reason is often manifested by a change in the patient's feelings towards his friends and relations. A youth who had been confined in an asylum, and whose insanity consisted in a complete perversion of his feelings towards those whom he ought most to respect, suddenly exclaimed, in the presence of the surgeon of the establishment where he was confined, "I love my father." This exhibited so entire an alteration in his mode of feeling, that it was considered as symptomatic of returning mental health, and by judicious moral treatment he soon recovered. "There is a stage (says Dr. Gooch) in insanity, approaching convalescence, in which the bodily disease is lessening its hold over the mental faculties, and in which the latter are capable of being drawn out of the former by judicious appeals to the mind."

"Convalescence from insanity," says Dr. Conolly, "like convalescence from a lingering fever, is a state intermediate between disease and health; and very slight circumstances may retard or promote the patient's perfect restoration." A patient, who had been labouring under a religious delusion of mind, had exhibited symptoms of amendment, and was allowed, accordingly, admission into the convalescent ward. Here he unfortunately met a patient whose insanity had manifested itself in a similar manner, and the two lunatics, who were considered to be nearly well, relapsed into their former state, and the mental delusion became as strong as ever." This case shews the importance of adopting a stricter classification of patients. "So long as one lunatic associates with another lunatic," says Dr. Conolly, "supposing the case to be curable, so long must the chances of restoration to sanity be very materially diminished. Convalescents should not even associate with convalescents, except under strict watching of persons of sound mind. The religious despair of a patient in the next apartment brings back and confirms the religious despondency of his neighbour in this: the passions and violence of those who are parading in the airing grounds revive the passions and ravings of those who are becoming more tranquil.

In insanity, moral treatment is beneficial in proportion as it is had recourse to in the early stage, and in the stage of convalescence. If medical men can be induced to believe that the least deviation from sound mind ought to be considered and treated as a disease or disorder of the mental function, much suffering and dis-

tress might be prevented by proper treatment. We must apply to the diseases of the brain and its manifestations, the same principles which we take as our guide in elucidating disease of any other organ. The slightest irregularity, uncasiness, and imperfection, in the function of the liver or stomach, is considered as a disorder requiring medical assistance: the same principles of practice must be applied to cases of mental impairment.

It is a well-established fact, that for one who has become insane from the exercise of his mind, at least a hundred has become deranged from the undue indulgence of their feelings. In persons predisposed to insanity, or who manifest some slight indication of disease, how important is it to endeavour to call into exercise the higher faculties of the mind—the judgment, reasoning powers, memory, reflection, &c.; and thus prevent the intellect from being thrown off its balance. There is much wisdom in Lord Bacon's advice, that "If a man's wits be wandering, he should study the mathematics."

The beneficial effect of recalling by the mind, when the body is prostrated by disease, pleasing associations, is beautifully illustrated in an anecdote related by Dr. Rush, the American physician. He says, "During the time that I passed at a country school, in Cecil county, Maryland, I often went on a holiday, with my school-mates, to see an eagle's nest on the summit of a dead tree in the neighbourhood of the school, during the time of the incubation of the bird. The daughter of the farmer in whose field the tree stood, and with whom I became acquainted, married, and settled in this city about 40 years ago. In our occasional interviews, we now and then spoke of the innocent haunts and rural pleasures of our youth, and, among others, of the eagle's nest in her father's field. A few years ago, I was called to visit this woman when she was in the lowest stage of typhus fever. Upon entering the room, I caught her eye, and, with a cheerful tone of voice, said only, "The eagle's nest." She seized my hand, without being able to speak, and discovered strong emotions of pleasure in her countenance; probably from a sudden association of all her early domestic connexions and enjoyments with the words which I uttered. From that time she began to recover."

An illustration similar to the one recorded by Dr. Rush, is related by Sir John Malcolm, in his interesting sketch of his friend Dr. Leyden. Sir John observes, speaking of the Doctor, that his love of the place of his nativity was a passion in which he had always a pride, and which, in India, he cherished with

the fondest enthusiasm. I once went to see him when he was very ill, and had been confined to his bed for many days. He inquired if I had any news. I told him I had a letter from Eskdale; and "What are they about on the Borders?" he asked. "A curious circumstance (I replied) is stated in my letter;" and I read him a passage which described the conduct of our volunteers, on a fire being kindled by mistake at one of the beacons. This letter mentioned, that the moment the blaze, which was the signal of invasion, was seen, the mountaineers hastened to their rendezvous, and those of Liddisdale swam the Liddal river to reach it. They were assembled (though several of their houses were at a distance of six or seven miles) in two hours, and at break of day marched into the town (a distance of about twenty miles from the place of assembly) to the Border tune of "*Wha da meddle wi' me?*" Leyden's countenance became animated as Sir John proceeded with this detail, and at its close, although the Doctor had been previously too weak to rise from his bed without assistance, he sprung out on the floor, and with strange melody, and still stranger gesticulation, sung aloud, "*Wha da meddle wi' me—wha da meddle wi' me?*" and from this day a sensible amendment took place, and he soon recovered from the effects of the malady under which he was labouring.

Dr. Armstrong, who knew well the importance of attending to the mind of the patient, said to Dr. Boot, a short period before his death, "Bōot, remember to be always cheerful in your intercourse with the sick; it takes a load from the heart, and infuses into it hope and confidence." Dr. Nichols, in his *De Anima Medica*, says, that whatever a man's distemper was, he would not attend him as a physician if his mind was not at ease; for he believed that no medicine would have any influence under these circumstances. He once attended a man in trade, upon whom he found none of the medicine he prescribed have any effect. He asked the man's wife privately, whether his affairs were not in a bad way? She said, "No." He continued his attendance some time, still without success. At length the man's wife told him she had discovered that his mind was much troubled by his pecuniary difficulties. When Dr. Goldsmith was dying, Dr. Turton said to him, "Your pulse is in greater disorder than it should be; is your mind at ease?" The poet answered it was not, and he feared that his death had been accelerated thereby.

In some cases of mental derangement, and in many low nervous diseases, the cheering influence of music might be had recourse to with advantage. In some pe-

culiar conditions of mind it has been known to exercise a highly beneficial influence. The attachment of the inhabitants of Switzerland to their native soil, notwithstanding the severity of the climate, is proverbial. It is well known, that when the Swiss are separated from their own mountainous and bleak wilds for any length of time, they are attacked with a disease termed *nostalgia*, which in former days was attended by serious and often fatal consequences. In Switzerland there is a favourite dance which the young shepherds perform to a tune played on a sort of bag-pipe. It is of a wild and irregular character, but so intoxicated are the lower order of Swiss with it, that if they hear it played while on foreign service, it causes such an intense desire to revisit their native homes, that, if not gratified, disease and death have often been known to result. So powerful an effect had this music on the Swiss troops, that orders were issued to the French army that the tune was not to be played in the Swiss regiments on the pain of death.

The influence which music is said to have upon the body, through the medium of the mind, is explained in two different ways. In the first place, a soothing effect is produced by the monotony of the sound, similar to what is well known to result from listening to the gurgle of a mimic cataract of some mountain rill, or to that of any water-fall. How often has the music caused by the waves gently dashing upon the beach, produced sleep, when all our narcotics have failed in producing a similar effect. This soporific effect of the repetition or monotony of sound, is beautifully alluded to by Mackenzie, in his *Man of Feeling*. When his hero, Mr. Harley, arrives in London, he finds that the noise and varied excitement of the metropolis increases his nervous state of habit, and prevent him from sleeping. Ordinary narcotics produce no effect upon him, and he must have continued to suffer from watchfulness if he had not happily touched his shoe-buckle, which lay upon the table; when the vibration produced a monotonous sound so closely resembling the voice of his good aunt, who nightly read him asleep in the country, that from that time he regularly applied to the same narcotic, and always slept soundly. Music acts, secondly, by causing an association of agreeable ideas. A lady who was confined in an asylum in the vicinity of London, and who had been separated for some months from her home and from all she held dear, was proved partially convalescent. She was, however, still melancholy, and it was suggested by her father that a piece, of which she was passionately fond, and which was associated with the

happiest period of her life, should be played within her hearing. This was done; and the medical gentleman who related this circumstance to me was present during the performance of the experiment, and carefully watched the result.

The effect produced was highly gratifying. For the first few minutes she took no notice of the music; in a short period a smile was seen to play upon a countenance where all had been dark and gloomy for months. As the music continued to be played, the effect produced was more sensible and powerful; ideas of a most pleasurable kind appeared to crowd upon a mind which had previously been a blank; a chord had been touched which vibrated through her until she appeared absorbed in the pleasing associations which the favourite tune had caused, and a joy was excited which, too intense for conventional modes of expression, represented itself in those quickly varied attitudes and lively motions whereby childhood exhibits its delight. This patient, in a very short period, was sent home completely restored to health.

We are told that the disease of Saul was alleviated by David's harp. Gibbon, in his work on the Decline and Fall of the Roman Empire, observes, that "Experience has proved that the mechanical operation of sounds, by quickening the circulation of the blood and spirits, will act on the human machine more forcibly than the eloquence of reason and honour."

In illustration of this observation, the following anecdote has been related. At the battle of Quebec, in April 1760, while the British troops were retreating in great confusion, the General complained to a field-officer of Fraser's regiment, of the bad behaviour of his corps. "Sir," answered he, with great warmth, "you did very wrong in forbidding the bagpipes to play this morning; nothing encourages Highlanders so much in the day of action—nay, even now they would be of use." "Let them blow, then, like the devil," replied the General, "if it will bring back the men." The pipes were ordered to play a favourite martial air. The Highlanders, the moment they heard the music, returned and formed with alacrity, and fought like infuriated lions.

We have the authority of Aristotle, that actual madness in horses may be cured by the melody of flutes; and Shakspeare, that music will put a stop to the gambols of a herd of wild unmanageable colts. Bonnet says, in his History of Music, that an officer being shut up in the Bastille, had his lute allowed him; upon which, after a trial or two, the mice came issuing from

their holes, and the spiders, suspending themselves from their threads, assembled round him to enjoy his melody.

We have several well-authenticated cases recorded, of monomania being cured by the patient being tricked out of his delusion of mind. Boerhaave mentions the case of a madman, who took it into his head not to make water any more, fearful of inundating the town in which he resided. This folly would have caused his death, if the physician had not bethought of creating, within the patient's hearing, an alarm that the town was on fire, and that nothing could save the inhabitants from ruin unless he would have the goodness to expel his urine to extinguish the conflagration. This reason appeared so logical to the monomaniac, that he made water and was cured.

A celebrated French writer on insanity mentions the following cases:—

A lunatic refused to eat; he had made a vow, and was bound in honour to abstain from food. After many days employed in the attempt to persuade him of his mistake, a pretended order was brought, signed by his revenger, who commanded him to break through his resolution, and promised him a guarantee against any reproach on that account. After a moral struggle of some hours he gave way with reluctance, took food, and was restored. Another individual, who had become insane in consequence of the political events of 1813, was informed of the revolution which occurred in the following year. He refused to believe until he was led by his physician into the midst of the foreign troops which surrounded Paris. He was convinced, and almost immediately cured.

Insanity caused by erroneous views of religion occurs most commonly in young persons of acutely susceptible feeling, and requires the most delicate and cautious management. Two modes of treatment are adopted in regard to it, and both equally erroneous. The one consists in hurrying the individual into the distraction of company, or a rapid journey. The other in urging religious discussions, and books of profound divinity. Both courses are attended with bad results, particularly the latter; for every attempt to discuss the important subject to which the distorted impression refers, only serves to fix the hallucination more deeply. The mode of treatment recommended by Dr. Abercrombie, under these circumstances, consists in enforcing regular exercise, paying attention to the general health, and suggesting a course of reading of a nature likely to fix the mind, and carry it forward in a connected train. Light read-

ing, or mere amusement, will not answer the purpose. A regular course of history appears to succeed the best; and fixing the attention, by writing out the dates and leading events in the form of a table. When the mind has thus been gradually exercised for some time, in a connected train of thought, it is often astonishing to observe how it will return to the subject which had entirely overpowered it, with a complete dissipation of former erroneous impressions.

It is questionable whether, in these cases, travelling is productive of advantage. It was observed to Aristotle, that a particular friend had derived no benefit from his travels. "That is owing," he replied, "to his having travelled along with himself." It is not easy to "pluck from the memory a rooted sorrow."

How much a medical man's success in the treatment of disease depends upon his being able to inspire and to secure the confidence of the patient! Implied faith between the patient and the doctor is the sheet anchor of both. Take this, and it will make you whole—is a cordial to the heart. By faith John Hunter's pill cured timid bridegrooms, and dissipated refractory gonorrhœas. An ague, which has defied a College, has vanished before the spell of a village witch.

A patient, who bore about him a mortal malady, surrendered himself into the hands of a quack, with an understanding that he was not to expect a change before six months. A friend, who saw the daily fee, and daily deceit, expostulated with the deluded man, who exclaimed, "For God's sake destroy not the hopes that man holds out to me; upon them I live, without them I die!"

An eminent physician has justly observed, that the person in whom there is the least fear of dying, has, *ceteris paribus*, the fairest chance to survive; so powerful a tonic influence has hope upon the body. Hope is a modification of joy, or rather joy by anticipation. This passion, or affection of the mind, is so pleasing and invigorating, that it is emphatically styled the "balm of life." It preserves the mind from stagnating in its present possessions, corrects the uneasiness of desire, and animates it to struggle with the difficulties it may have to encounter. He who gave away all he had, and reserved only hope, made not so ill a bargain as may be imagined; he took for himself that which is sweetest in life. How often do we see sickness, which has resisted the ordinary means of cure, yield solely to the influence of the mind, reposing confidence in the pretending impostures or some, or

the supposed sanctity and efficacy of prayers and good works of others. Hence the observation of an eminent writer, who says, "The physician is often the poet, the artist, the third son of Apollo, and begotten only under the influence of mild constellations. He that depends on medicine alone, as such, seeks corn in thrashed sheaves. Medicine," he continues, "is but an instrument of cure; but the physician heals not by it alone, but by the glance of the eye and the animating word."

In cases of melancholy, much good is often to be effected by moral treatment. Of course the mode adopted must be in accordance with the peculiarities of each individual case. I will admit the difficulty of reasoning a man into cheerfulness of mind. It is easy to say to the sad, be happy; but it is no easy thing to drive out of his mind the delusions which have taken such forcible possession of its faculties.

It is obvious that there is a large scope for the management of the mind and passions in these cases. The great point is to endeavour to interrupt the attention of the mind to its accustomed object. To effect this much judgment is required. Most hypochondriacs are jealous of being considered as such, and have generally a great opinion of their own wisdom and sagacity, and are apt to hold very cheap the common amusements of life, especially those connected with social intercourse and company, particularly as they are inclined to think themselves neglected and despised by the world.

I think, in these cases, it is advisable not to contradict too preemptorily the ideas or opinions of the patient; opposition, if too direct, serves only to irritate the temper, and to confirm erroneous opinions. Such a degree of compliance as expresses only a moderate assent, often succeeds. It has been recommended to excite such passions as are of an opposite nature to those that have prevailed during the course of the disorder. Travelling, music, cheerful entertaining conversation, often effect much good in these cases, when no physical agents can bring about a favourable result. "Beware," says Dr. Burrows, "of giving a hypochondriac reason to think his mind is deranged; it is the surest way to make it so. Neither ridicule his predilection for adopting all sorts of remedies, for it will forfeit his confidence in you, and either make him relinquish all means of cure, or drive him to empiricism. It is often," says the same authority, "prudent to treat an imaginary disease as if it were real."

Much good is to be effected by the

cheerful conversation and encouragement of a sensible friend, who has tact enough to rouse the other faculties into activity, and to withdraw dexterously the patient's attention from dwelling on his delusion. The sound faculties are thus brought into play and strengthened, new interests are excited, and a temporary oblivion of his distresses takes place, which, as allowing the morbid organs time to rest, is extremely favourable to recovery.

How awful and terrible is that man's situation, deprived of the cheering and elevating influence of this passion. It was once my lot to witness the case of a maniac whose derangement of mind consisted in his having abandoned himself to despair. He laboured under no distinct and prominent delusion, but his disease was simply a total absence of all hope. The iron had entered his very soul; he appeared as if the hand of a relentless destiny had written on the threshold of his door, as on the gate of the infernal region of Dante, this heart-rending sentence—"Abandon all hope."

Aretæus, fully sensible of the necessity of supporting the strength of the system, and how much this depends upon the spirits, expressly counsels the patient to be of good heart; and advises the physician to entertain him with such discourse as might tend to encourage his hopes of recovery. This celebrated physician has given minute instructions connected with the moral treatment of disease, which he considered of great importance in practice. In particular affections of the nervous system, he directs that the eyes of the patient should be entertained with the sight of plants, paintings, and he should be amused with the cheerful discourse of his attendants. He farther recommends, that the bed of the patient should be placed near a window commanding a beautiful prospect: he directs the chamber to be strewn with flowers, so as to resemble the face of the country in the spring. He suggests the introduction of music, and that amusing books should be read aloud to the patient, in order to prevent his mind from dwelling on his disease, and thus preventing his recovery.

[We regret that the length of the preceding paper precludes our giving the author's remarks on the benefits to be derived in cases of mental disease and nervous affections by powerfully rousing the mind; as well as his observations on the effects of the imagination on the fœtus in utero.—*Ed. Gaz.*]

THREE CASES OF ABORTION, WITH SYMPTOMS OF POISONING, *Produced by the use of Rue.*

By M. TH. HÉLIE.

CASE I.—A young girl of very short stature, but of robust constitution, who had had a very difficult labour at the age of sixteen, brought on a miscarriage in the third or fourth month of pregnancy, in the following manner, as she confessed:—She sliced three fresh roots of rue, as big as her finger, and boiled them in a pound and a half of water down to three cupfuls, which she took in the evening at a draught. She was immediately seized with a dreadful pain in her stomach, which was soon followed by so great and general a disorder that she thought she was going to die; she saw every thing through a cloud, tottered, and felt giddy, and, as it were, intoxicated. Soon afterwards there were violent and continual efforts to vomit, but she only brought up a little blood. This state lasted the whole night. On the following day the symptoms diminished, and at the same time she began to experience colic, which was slight at first and more severe afterwards, the fits being separated by long intervals. Towards the evening of the second day they became violent, and followed one another in quick succession. There was now a small discharge of blood, then large clots were thrown off, and abortion took place with ease in a few minutes, forty-eight hours after the decoction of rue had been swallowed, the girl not having been confined to her bed. The symptoms caused by the rue went off in a few days.

CASE II.—Maria —, aged 23, a servant in town, had been in the country with a farmer for five days, to get well of an indisposition with which, she said, she had been recently attacked. During the first two days she went out, and had a good appetite. On the third day she was suddenly seized with continual vomiting, which was difficult and painful. There was considerable fever and thirst, and she drank a large quantity of service-cider* and wine-and-water, which she immediately vomited up. The vomiting had now lasted two days, accompanied by great weakness, twisting movements of the limbs and trunk, rotatory movements of the head, and delirium, or rather reverie, when M. Hélie saw the patient, on the 5th December, 1835. She was then in a sleepy state, from which she was easily roused; she answered questions well, but

* A drink is made in some parts of France from the fruit of the service-tree.—*Translator's Note.*

with slowness and some difficulty; the eyes were injected, the face somewhat coloured, and without expression: one might have said that she was drunk. Her sight was dim, the pupil contracted, some fever, with a large and soft pulse, and but little heat of skin. The urine had been suppressed since the vomiting had begun, and there were no alvine evacuations. The tongue was somewhat red just at the edges; the epigastrium was slightly painful. On feeling the abdomen, Dr. Hélié perceived that the patient was about seven months pregnant. The pertinacity of the girl in denying her pregnancy, and this sudden attack of vomiting, accompanied by unusual symptoms, led Dr. Hélié to suspect the employment of some drug to procure abortion; but his inquiries were for the time fruitless. There was nothing to announce the beginning of labour; the abdomen was quite yielding, and there was no discharge. On the other hand, her general plumpness and good complexion forbade the supposition that there was some recent disease. He therefore confined himself to prohibiting the hurtful drinks which the patient had been using for the last two days, and to prescribing a decoction of barley, with low diet, &c.

The vomiting was soon allayed, but all the other symptoms continued. On the morning of the 6th she seemed to suffer still more. At eleven o'clock, her face, her general state, and all the symptoms, were the same as on the previous day, but of diminished intensity. On raising the bed clothes, M. Hélié was struck with the characteristic odour of parturition; and between her thighs there were two children, still attached to the placenta, which had also been thrown off. They seemed to have reached six and a half or seven months of foetal existence, but one was much larger than the other. They were both dead, but there was nothing to shew that they had lived after their birth, nor was there any trace of external violence. There was a considerable quantity of blood and water in the bed; the uterus was well contracted. The pains, according to the girl's account, had begun the day before, and delivery had taken place an hour preceding this visit; and though it had been very painful at the moment, several persons present in the room had not the least suspicion of it. This day and the next produced but little change in the symptoms. There was still a state of somnolence and stupor, reverie, movements and twisting of the limbs, and frequent moans; stools and urine were passed, and the lochia flowed. She took roast meat in wine, according to country usage.

On the evening of the 8th there was swelling of the breasts, with fever, delirium, and convulsive movements of the limbs, which were both violent and continual: until this period Maria had not been very ill. In consequence of this exacerbation she fell into a state of extreme debility; the vomiting returned, the matter brought up consisting of green bile, and of food and drink, which were thrown up as soon as swallowed.

On the 9th, the symptoms increased, and there was distension of the abdomen. On the morning of the 10th, there was extreme weakness, prostration, somnolence, stupor, an intoxicated expression of countenance, and frequent moaning, with the articulation of a few monosyllables; there was also reverie, with subdelirium, and there had been for the last two days enormous swelling of the tongue, which was red, but covered with a thick whitish coat. The pupil was constantly contracted, the eyes dull, the vision confused, the pulse feeble, soft, very small, and beating only thirty times in the minute, but regular; the temperature of the skin was below the healthy standard. The arms were affected with a twisting motion, and the head rolled to the right and left. The epigastrium was tender or pressure, but the rest of the abdomen was supple and not painful. The uterus had returned to its natural situation. There were continual bilious vomitings; the patient refused to eat or drink, and had grown sensibly thinner; the lochia were suppressed. These symptoms, unaccompanied by peritonitis, strengthened Dr. Hélié's belief that abortion had been excited by some narcotico-acrid substance. In fact, he learned that Maria had taken a decoction of rue leaves, without being able to ascertain in what dose or how many days she had employed it.

On the two following days, the 11th and 12th, the state of the patient was nearly the same. Two large blisters had been applied to the thighs, and cataplasms to the epigastrium; barley-water had been prescribed for drink; and, on account of her extreme weakness, a few spoonfuls of light broth, which was at first vomited, but afterwards retained: two blisters were then applied to the legs, and cold sugar and water was given for drink.

There was afterwards some mitigation of the symptoms.

On the 13th there was a remarkable change: the symptoms of poisoning gradually went off, and were changed into those of typhus fever, the disease not becoming less serious.

On the following days, a considerable improvement took place; the tongue returned to its natural state; the salivation

stopped; the convulsion of the limbs ceased; the understanding seemed less obtuse; the pulse remained equally weak and slow, but the skin was no longer cold. There was an attack of fever every evening, and vomiting when the paroxysm came on, but at no other time. The urine continued to pass involuntarily, but no longer accumulated in the bladder. The lochia had returned. She was ordered to take milk as her sole aliment, and gum-water with milk. The improvement continued; the typhoid state went off in a few days; and the evening febrile attacks did not return. The abdomen yielded to pressure, and was not tender; but there was obstinate constipation for some days, which was overcome by two ounces of manna. The urine now ceased to flow involuntarily; the face regained its natural expression, and the understanding its powers. The slowness of the pulse was one of the symptoms which lasted the longest.

On the 30th of December Maria returned to service, and some days afterwards was able to work again.

CASE III.—A young girl, being four or five months pregnant, and wishing to induce abortion, took for several days a large dose of the expressed juice of fresh rue leaves. She experienced symptoms quite resembling those of the preceding case, and was in great danger. When she was at the worst, among other symptoms were observed prostration, somnolence, excessive general debility, frequent fainting, extreme smallness, weakness, and slowness of the pulse, extraordinary coldness of the skin, and continual non-convulsive movements of the limbs, particularly the arms. As in the preceding case, there came on active inflammation, and considerable swelling of the tongue, with copious salivation. For several days abortion was seen to be coming on, but the fœtus was not expelled till towards the sixth day, dating from the beginning of the symptoms of poisoning. When abortion had taken place, all the symptoms grew milder, and no inflammation of the uterus followed. The symptoms of poisoning, however, lasted at least twelve days, and went off gradually. The girl recovered slowly. — *Annales d'Hygiène*, vol. xx.

STRUCTURE OF THE INFUSORIA.

IN the last number of Müller's Archiv. is a paper of M. Mayen, giving the results of his microscopic observations on the infusoria. If his views are confirmed by

other inquirers, the whole organization of the polygastrica must have been laid down erroneously by Professor Ehrenberg, whose account of them has been admitted into all works on natural history. We have here a striking proof of how rarely any two microscopic observers can manage to see the same thing. It will be seen that M. Mayen entirely denies the existence of the minute stomachs, as asserted by Ehrenberg.

Natural historians are aware, that as early as in the year 1781, V. Gleichen added carmine to fluid containing infusory animalcules; and on the following day observed, that they showed several red globules in the interior of their bodies, from which he inferred that the animalcules had swallowed the colouring matter. He also observed that these globules disappeared again through a special opening. Professor Ehrenberg has more lately repeated these experiments, and drawn from them the conclusion, that the infusory animalcules in question possess a greater or smaller number of stomachs, which in some families communicate with each other by means of a common alimentary tube, in a manner differing in different species. In consequence of these discoveries these infusoria received the names of polygastrica. Professor Ehrenberg had observed these stomachs became filled in succession, and has even given representations of the alimentary canal which lies between and unites them.

M. Mayen has never subscribed to those views; first, because he could never see the alimentary canals said to unite the stomachs; and secondly, because he has seen the stomachs moved about with greater or less celerity, just like the globules in the rotatory motion which is carried on in the cells of the charæ. At a later period, he observed in the vorticellæ, that when they had from nine to fifteen large indigo globules in their body they regularly turned around a fixed central point, so that in them an alimentary canal uniting the stomachs and opening at the mouth and at arms could not exist. What, then, are those pretty large globules and bladders which are found in the interior of the infusoria? This question M. Mayen has put to himself, and has been enabled to answer by making continued observations on the subject.

The true infusoria are bladder-like creatures, whose cavity is filled with a mucous saltish substance. The thickness of the membrane forming the bladders, can, in some of these creatures, be clearly determined; and M. Mayen has, in some of its families, observed in this membrane a well-marked spiral structure, so that in

most particulars the structure of these infusoria resembles that of the cells of plants. In the larger infusoria there passes from the opening of the mouth a cylindrical (alimentary) canal obliquely through the membrane forming the animal; the extreme end of this canal expands itself to a greater or less degree when nourishment is taken in, but usually to the size of the globules which are seen in the interior of these creatures. The inner surface of this part of the alimentary canal is clothed with cilia, by whose motion nutritious and foreign substances, which are taken in, are moved about in circles with great celerity, until they are rolled into the form of a regular globule. During this formation of the globules, the stomach (for the organ in question can only be taken for the stomach) is openly united to the alimentary canal, and by the exterior ciliary apparatus new matter is always drawn into this canal, and as far as to the stomach; but whether the alimentary canal between the opening at the mouth and the stomach is also covered with cilia, M. Meyen has not yet been able to determine.

When, then, the globules of the matter taken in have attained the size of the stomach, they are pushed through at the other end, and driven into the stomach of the animalcule, whereon a new ball immediately forms itself within the mouth of the alimentary tube, if any firm matter be present in the enveloping fluid: this second ball is sent into the stomach of the animalcule in like manner, and now pushes before it the first ball along with the mucus lying between them, and so the formation of similar globules proceeds.

It was from these globules that Professor Ehrenberg inferred the existence of the great number of stomachs. If in the fluid enveloping the animalcule there is little matter of a firm consistence, then the globules are also less firm, and they are similar in appearance to those which are commonly observed in infusoria in an uncoloured fluid; and in them such a globule shews only a few small particles of solid matter, and consists chiefly of the mucous fluid, which assists in rolling together particles of firmer consistence, when present. Sometimes such soft globules are pressed together so forcibly by the strong contractions of the animalcule, that they remain so united.

Whoever wishes to observe very clearly the formation of these globules, must begin his observations immediately on the infusoria being placed in relation to the coloured fluid, as the colouring matter is very quickly taken in, the process often beginning after half a minute. One can then observe how one globule

after another passes perfectly formed out of the alimentary canal—is pushed down on the inner wall of the stomach of the animalcule (just as in the paramocia, keronia, and vorticellæ)—how then new globules press the old ones forward along with the mucus lying between them, so that the first formed soon begins to rise up on the opposite wall of the stomach, turns itself round at the opposite end of it, and then is pushed down again on the other side; and so the number of these (revolving) balls increases, until some of them are thrust out at the anus.

The number of these globules is sometimes so great, that the whole cavity of the animalcule is filled with them, and that they lie so close on each other, that they altogether form one large uniform mass, which often (especially in the vorticellæ) slowly moves round on its centre. This motion of revolution M. Meyen has ascertained to be caused by the force with which the new balls, formed from time to time, are pushed into the stomach, and act on the lower surface of the ball of globules. In other cases, where so many globules are not present, that circular motion of globules round a central point (already alluded to in the beginning of this paper) is displayed; but the causes of this motion are uncertain.

In short, in the true infusoria, the matter which they can take in is brought into their stomach in the form of globules; and here the nutritious portion is extracted from them. The unnutritious portion passes away usually in just the same globules as those in which it entered; but the mucus lying between them is commonly reabsorbed, and in some few cases the particles of matter to be excreted begin to separate from the globules while in the stomach.

But what, then, are the bladder-like cavities which often occur in so large number, and of such different sizes, in the interior of the infusoria? They are certainly not stomachs, as they exercise no action on the globules of which we have hitherto spoken, although occasionally a few reach the stomach among the globules. We can observe the formation of these cavities, and also their sudden and complete disappearance in the mucous fluid in the interior of the infusoria, just as well as the formation of the globules; we can even see such a cavity form itself around one of the globules, and then disappear again after a time. The microscope shews that these cavities have no special membranous walls, but consist purely in a hollowing out of the mucous substance. They also usually occur on the inner surface of the membrane which forms the walls of the

animalcule; and sometimes they enlarge to such a size, that such a bladder forms from a third to a half of the cavity of the whole animalcule. The slight refraction of the rays of light falling on their edges, shews that these cavities, or stomachs of Ehrenberg, contain a thin and watery fluid, and are not filled with air; and in the larger infusoria it can be distinctly seen that they do not open externally. Similar cavities are formed in the mucus of the cells of plants, and are especially common in some of the aquatic thread frangi, or hyphomycetes, in Martius's system.

M. Meyen regrets that his botanical labours prevent him from carrying the subject further out at present, but hopes that these observations will lead others to a more thorough examination of the subject.

[The only obscurity in the paper of M. Meyen arises from the use of the words *magen* and *köhle*. It is presumed that M. Meyen believes that the digestive organs of the infusoria consist of a tube expanding to form a stomach, and contracting again before ending in the anus. *Magen* has therefore been translated, alimentary canal; and *köhle*, stomach.—TRANSLATOR.]

THERAPEUTIC USES OF VINEGAR.

THE use made of vinegar in common life is sufficient to shew its refrigerant power. Every one knows that when habitually taken, it produces leanness, from a sort of languor of the digestive passages. Some persons have used it successfully against certain kinds of dyspepsia, which may easily be accounted for, if the disorder was of a kind to require antiphlogistic remedies. In a healthy man vinegar increases the perspiration and urine. When given in a large dose it obviously weakens the powers of life, lowers the pulse, and causes lassitude in the limbs. Its action is consequently the contrary of that of wine; and vinegar is, in fact, an excellent means of correcting the action of wine, many practitioners affirming that it is one of the best remedies for speedily dispelling the intoxication caused by alcohol.

These data are sufficient to prove the lowering property of vinegar; but there are other facts which may be cited on the same side.

Every one knows that vinegar is useful against the narcotism produced by opium; this effect is purely physiological, and may be easily explained by the lowering property of vinegar; for the action of opium being stimulant and congestive, vinegar

counteracts it, as bleeding, or any other antiphlogistic would. Chemists fancy that in such cases the vinegar acts upon the opium, and forms an acetate of morphia, but it is not so; for the opium is no longer chemically accessible, the moment it has produced its narcotic effect, as it is then already absorbed, and has passed into the blood; and, moreover, if the supposed acetate were really formed, it would be as narcotic as the opium.

Hippocrates knew the refreshing powers of vinegar so well, that he prescribed it against inflammatory fevers in the forms of vinegar and water, oxycrat, (syrup of vinegar), and oxymel. Many patients drink these beverages with avidity, especially in summer, and are much benefited by them, when their diseases are of a kind requiring antiphlogistic treatment.

In 1790, Leonessa of Padua publicly treated a patient labouring under hydrophobia with large doses of vinegar, and asserts that he cured him, although the malady was already developed. He gave a pound a day, divided into four doses. This cure may be explained by the strong contra-stimulant power of vinegar; and hence other physicians have obtained the same result by means of belladonna in large doses.

In other cases of hydrophobia vinegar has been given without success; yet neither the fact just mentioned, nor the lowering power of the remedy, can be disputed.

Mental aberration has been combated with vinegar; and good effects have been produced when the disease was of a kind to yield to antiphlogistics: in such cases the remedy has been given in the dose of several ounces a day, after meals. Long experience has taught us that oxymel is an excellent expectorant, both in acute and chronic inflammation of the chest; and some practitioners have even prescribed vinegar with advantage in phthisis. Nevertheless, it is generally avoided in these cases, because vinegar is said to irritate the chest, and excite coughing; but this is a prejudice which it is right to resist. It is not true that vinegar irritates the chest, but its contact with the back of the palate during deglutition titillates the mucous membrane, and sometimes excites coughing; but this mechanical effect may be easily avoided by giving the medicine in a gummy potion, or in the form of syrup, or of oxymel. In inflammatory diseases, fomentations with water mixed with a good deal of vinegar are doubly useful, both by the absorption of the vinegar, and by the refrigerating evaporation which they produce.

The Roman armies, during their cam-

paings in the East, carried with them a stock of vinegar, with the twofold object of quenching the soldiers' thirst when the weather was very hot, and preserving them from intermittent fever.—(*Végetius de Re Militari.*)

The English have copied the Romans in this point, and with great advantage.—(*Pringle.*) The preceding considerations give the reason why.

The reader will now see how absurd is the theory of some toxicologists, who prescribe vinegar and the other acids in many kinds of poisoning, as, for instance, when it arises from belladonna; for their practice is founded on a false analogy drawn from the poisonous effects of opium. We have just seen, indeed, that in the latter case vinegar is useful; but we shall shew that in poisoning by belladonna, and many other drugs, it is hurtful, because it pulls the same way with the poison. We shall terminate these observations by borrowing the following case from Portal:—

"A few years ago, a young lady, in easy circumstances, enjoyed perfect health; she was very plump, had a good appetite, and a complexion blooming with roses and lilies. She began to look upon her plumpness with suspicion, for her mother was very fat, and she was afraid of becoming like her. Accordingly she consulted a woman, who advised her to drink a small glass of vinegar daily: the young lady followed her advice, and her plumpness diminished. She was delighted with the success of the remedy, and continued it for more than a month. She began to have a cough, but it was dry at its commencement, and was considered as a slight cold which would go off. Meantime, from dry it became moist; a slow fever came on, and a difficulty of breathing; her body became lean and wasted away; night sweats, swelling of the feet and of the legs succeeded, and a diarrhoea terminated her life. On examination, all the lobes of the lungs were found filled with tubercles, and somewhat resembled a bunch of grapes."—*Gazette Hôpitaux*; from a *Treatise on the Materia Medica*, by Professor Giacomini, of Padua.

HUMAN BODY RENDERED LUMINOUS BY PHOSPHORUS.

A CASE of glanders in the human subject recently occurred at the Hôtel Dieu, Paris. The treatment consisted chiefly in the exhibition of phosphorus externally and internally. The only result mentioned in the report of the case is such a degree of phosphorescence, that the body after death was sufficiently luminous to light up the *salle des morts*.—*Gazette des Hôpitaux*.

PATHOLOGY OF PORRIGO.

THE observations of Bassi and Audouin on the nature of muscardine—a disease to which silkworms are subject—had proved that it was owing to the growth of minute fungi on the animal. Professor Schoenlein, of Zurich, has been led to examine under the microscope some cutaneous eruptions. On the first examination of a pustule of porrigo lupinosa, he satisfied himself of the vegetable and fungous nature of the pustule. Professor Schoenlein is busily employed in prosecuting this subject, and means soon to publish the results of his investigations.—*Müller's Archiv.*

ROYAL COLLEGE OF SURGEONS.

JACKSONIAN PRIZE.

THE Jacksonian Prize for the year 1838 has been adjudged to Mr. Edwin Lee, of London, for a Dissertation—"On the Comparative Advantages of Lithotomy and Lithotripsy, and on the Circumstances under which one Method should be preferred to another."

APOTHECARIES' HALL.

LIST OF GENTLEMEN WHO HAVE RECEIVED CERTIFICATES.

Thursday, April 25.

William Blucher Dolton.—Thomas James Holmes, Lyme Regis.—Henry Obré, Gosport, Hants.—John Watson, Knaresborough, Yorkshire.—William Richard Edwin Smart, Devonport.—Francis Wm. Drake, Hadleigh, Suffolk.—Thomas Richard Collins Downes, Ludlow, Salop.—Lancelot Newton, Sawtry, Hants.—Edward Kingsford, Canterbury.—Walter Goodyer Barker, W. Tarring, near Worthing.—Ralph Montague Bernard, Clifton, Gloucestershire.—Henry Brickwell, Sawbridgeworth.—Joseph Bowers Gray, Queen's College, Cambridge.—James Hiley, Elland, Yorkshire.—Frederic Barham, London.—Frederick Dickenson Nightingale, Windsor.

URINARY SYSTEM.

By DR. VENABLES.

Diuresis saccharina—concluded.

DR. PROUT also mentions the necessity of attending to the thirst, and its consequences—the immoderate use of fluids. He says, there can be no doubt that the drink should be limited as much as possible, for if the patient be permitted to indulge *ad libitum*, we can scarcely hope for benefit from any remedy; and he observes, that patients under these circumstances suffer from “such a degree of mental imbecility, or want of stoicism, that they will frequently drink by stealth when they cannot for shame, or want of opportunity, do it openly*.” That patients should be indulged to a certain extent, and within due bounds, no one can pretend to deny. It would be not only cruel, but positively injurious, to subject the patient to all the tortures of thirst without some effort for his relief. It therefore becomes matter of inquiry—first, what are the drinks best suited to the circumstances; next, how the conditions upon which depends the insatiable desire for drink may be best corrected or relieved.

Arctæus has given a list of fluids which he states are best adapted for patients

suffering from diabetes: and first, he recommends water boiled with autumnal fruits*. He also recommends certain wines—astringent to strengthen the stomach, and undiluted to evaporate and dissipate the other humours†. The salt wines, he says, excite thirst, but the astringent ones are at the same time cooling, and also change the body, and induce a good habit‡. But even sweet wine, according to the same author, like the blood, invigorates; because it generates blood§.

Wines, however, in the present day, are not generally considered best adapted to the states of stomach usually prevalent in diabetic patients. From the state of the stomach, almost all the matters introduced undergo some species of fermentation: hence the sweet wines undergo the vinous fermentation, with the extrication of large and distressing quantities of gas; and the more astringent even undergo either the same, from the reaction of the astringent and vegetable matters upon any sugar which they may contain, or their alcohol becomes converted into acetic acid. Hence the burning pain and the acid eructations from which such patients suffer.

The Hotwells, and other waters of Bristol, have been long known and celebrated in diabetic diseases. Both Prout and Marsh speak favourably of them, and assert they appear to quench the thirst in these complaints much more efficaciously

* On the Urinary Organs, p. 77.

than any other drinks. Dr. Prout states, that he knew a patient labouring under confirmed diabetes, to drink very largely of the Leamington saline waters, without increasing the quantity of his urine, and yet apparently with some advantage to his health. The Hotwells of Bristol contain mostly carbonate of lime held in solution by an excess of carbonic acid. Now it is difficult to explain or even to conceive how these salines act, or, as Prout observes, "whether they really have any beneficial influence; yet, he says, small doses of carbonate of lime or of magnesia, which probably were first recommended on the faith of the beneficial action of the above waters, do occasionally seem to exert a temporary good effect in diabetes, by diminishing the thirst, and through this medium the quantity of drink and urine*." That such waters may occasionally be beneficial, can perhaps be explained upon the principle of the alkaline earths combining with and neutralizing the acids generated in the stomach in such debilitated states of it.

In many cases the addition of a little distilled spirits (brandy, for instance) gives a certain degree of tonic to the stomach, and prevents that tendency to fermentation to which all the ingesta are so liable upon introduction into the stomach; but after all, perhaps, there is nothing equal to pure water; and the purer it is (even distilled water) the better. I have found that when patients can be prevailed on to adopt this plan, they in general suffer less distress; and Prout states, that such waters agree well he has found by experience.

The various kinds of animal decoctions, better known as broths, soups, teas, may be allowed in cases of great debility and inordinate appetite for food. Milk, too, is a wholesome drink, and I think very often tends to allay thirst, and certainly nothing can be milder or less stimulating to the urinary organs. Aretæus† also speaks of milk, and recommends it to be taken with the food for nourishment. Tea, and more especially green tea, which seems to excite diuresis, should be avoided. I have known many persons disposed to diuresis state that tea, and much more powerfully if green, always excited a most copious discharge of urine; and two or three stated that, so powerful a diuretic did it prove with them, when in society, they could not taste it, as even half a cup produced an immediate and irresistible desire to void the urine. Therefore it is evident that such articles, as ex-

citants of uresis, should be carefully avoided.

Water, however, as the mildest beverage, is the best, and, as a general rule, all the drinks should be taken in a tepid state; first, because, as Dr. Prout well observes, the patient, whose craving is generally after cold drinks, will thus content himself with less; and, secondly, they should be taken at those periods, in preference to others, when the stomach is not loaded with solid food*. But there is still an additional reason, and of great importance, why the drink, and more especially if water, should be taken tepid—namely, the nausea which warm water induces, and this serves to relieve the sensation of thirst, and diminishes the necessity for so much drink. It is upon the principle of exciting nausea, also, that the class of emetics formerly mentioned prove useful in nauseating doses; and their agency in exciting the functions of the skin, by which the urinary discharge is reduced, give these remedies an additional claim upon our consideration.

The next subject is the nature of the diet; and various opinions have been entertained upon this question. Some are exclusively in favour of a mild vegetable diet of the farinaceous description; others adopt the opposite extreme, that the diet should be wholly animal, and vegetables altogether proscribed. It is probably evident to you what the grounds are upon which each of these doctrines is founded. They who look upon diabetes as a disease of excitement, or of an inflammatory character, naturally prefer that diet which powerfully tends to relieve or counteract the effects of such a diathesis. The opposite partly establish their doctrine partly upon chemical principles. Urea, a principle containing nearly half its weight of nitrogen, disappears, and its place is supplied by sugar—a principle containing no nitrogen whatever in its composition. Therefore, say they, the patient should be restricted to those articles for diet which furnish in greatest abundance the deficient principle. Both theories have had their advocates, and the practice founded on them has been tried, but in vain—that is, so far as effecting a perfect cure. With respect to an animal diet, Dr. Prout observes, "I have watched the effect of an exclusively animal diet on the urine of diabetic patients. In most instances it seems to lessen the quantity and deepen the colour of the urine, and thus to disguise the saccharine matter present; but as far as I have been able to ascertain, it does not diminish the specific gravity of this secretion†." I myself

* On the Urinary Organs, p. 79.

† Ibid. p. 80.

have paid some attention to this subject, and I am satisfied that a diet exclusively animal does not exert the slightest beneficial influence upon the disease; but, on the contrary, does a great deal of mischief, by inducing plethora and local congestions and inflammations of a fatal tendency—nor unfrequently sudden death. We have already noticed the voracious appetite, and this induces the patient to indulge to a most pernicious extent in a diet which both is agreeable to his palate and agrees well with the stomach. You will often hear a patient say, under such circumstances, “I feel as light again; my water is greatly reduced in quantity; and I now begin verily to believe I shall get well.” Fatal confidence! A very short time dispels the mist, and at once blasts all his hopes and expectations. Many, too, who are put upon an exclusively animal diet die suddenly apoplectic. “Indeed, I believe,” says Prout, “the greater number of cases of sudden death in this affection (which is by no means an uncommon termination of it) have been distinctly referrible to errors either in the quantity or quality of the food, or both; that is to say, the patient has been generally cut off after a *hearty meal*, as it is vulgarly termed.”

Therefore, in determining the quality of the diet, we have two things to consider: first, the tendency to plethoric and congestive diseases; secondly, the proneness to fermentation in the stomach, and to form unwholesome chyme or morbid chymification. The first is promoted by animal food, the latter by all vegetable matters; but by some, in a much more aggravated degree. Upon the whole, therefore, a mixed diet, consisting of animal and farinaceous matters, seems best adapted, and stale bread, and even the coarse hard brown biscuits, used by sailors on board of ship, I have seen agree with many dyspeptics much better than the best fermented wheaten bread. He should avoid as much as possible sweet and ascendent matters and fruits; also what have been termed raw or esculent vegetables, colworts, &c. Many of these articles contain a large proportion of nitrogen, and upon the animo-alimentary theory ought to prove beneficial; but yet, so far from this, they are found to increase the distress, by the flatulencies they produce, and thus aggravate all the other symptoms. But unfortunately for this theory, it is directly opposed to sound reasoning. Urea—a principle abounding in nitrogen—is deficient, consequently the system is not freed in the natural extent from this noxious agent; therefore, the obvious rule would be to lessen in every way the sources whence nitrogen is derived, and therefore would

lead us to a directly opposite conclusion and mode of practice. But further, it may be stated, that even in diabetes a considerable quantity of urea is at times generated and thrown off without any relief of the general symptoms, or alleviation of the disease. Therefore, evidently it is neither the absence of urea, nor the presence of sugar in the urine, that constitute the *summum mali*, and therefore are only to be looked upon as indications of those hidden conditions which produce the effects.

Some variety, too, of opinion has been entertained upon the nature of the animal food itself best suited. Some merely prescribe the ordinary animal diet, while others insist much upon a diet exclusively of animal fat; and it has been stated that very great benefit has been derived from the practice. This, however, might be explained upon very different principles. It is very well known that very few stomachs will bear a large quantity of fat or rich food. Such very soon cloy, and the appetite is satisfied comparatively with a very small proportion of food. Thus, advantage may have been derived from the effect such a diet has upon the appetite, and the quantity taken being thus considerably reduced. In considering diet and drink, the practitioner must direct his attention not merely to the quality, but to the quantity of the food; and that diet and those fluids selected which tend to reduce the distress, and keep the thirst and appetite within due bounds. “Were I to particularize the species of food, I should say generally that mutton or beef plainly cooked, and particularly mutton chops or beef steaks, rarely done, should be taken twice in the twenty-four hours; and that the other meals should consist of any simple article that can be prepared from farinaceous matters, with milk, eggs, &c. only*.”

The quantity of food is often determined by the frequency of the meals: thus many who eat but very little at a single meal, yet indulge so often, that on the whole they consume a very large quantity of food. Therefore it is often advisable to regulate the period of meals, and to interdict any indulgence in the intervals. This subject requires but little observation. A regulated quantity may be taken at intervals of five or six hours; but, of course, this will admit of modification; and in the earlier periods of the disease, and in the more acute forms, it will be sufficient to take animal food but once in the twenty-four hours. But there is one thing to be observed—that the circumstances of the case must be taken into consideration.

* Prout on the Urinary Organs, p. 80.

It would be dangerous, when a patient has been for a long time indulging in large quantities of food and drink, suddenly to reduce him to the proper standard; the prudent practitioner, therefore, will gradually, not too suddenly, reduce the quantity, till the due bounds have been attained. In the more chronic or protracted cases, where the strength has been much exhausted, animal food may be indulged in to a much greater extent, and much more frequently, and a little brandy allowed in the water, which perhaps is preferable to wine. With respect to regimen, the patient should be warmly clad; flannel should be worn next the skin, to promote the action of this organ; but, above all, he should be preserved from all mental anxiety, as nothing tends so much to aggravate the disease as a disturbed or excited state of mind. Exercise must be very cautiously employed, for the most serious mischief has arisen from want of caution upon this subject. In the acute forms, sometimes active exercise increases the irritation; and when debility is severe, sometimes syncope is produced even by the least exertion. To assist warm clothing in restoring the action of the skin, warm or vapour baths, with the use of the flesh-brush, are sometimes found beneficial.

We now come to consider whether there be any medicines capable of exerting any, and what peculiar agencies upon this disease. There are some certainly which reduce the quantity of urine, and that very considerably; but this appears to be the principal effect which they have upon the disease. With respect to the morbid qualities, they appear to remain unaffected; and, indeed, it seems very doubtful if there be any remedies that exert a specific effect of this description; if there be, they are not as yet known. Opium not only reduces the quantity of urine, but also greatly diminishes that nervous irritability from which diabetic patients so constantly suffer. Of the preparations of opium, Dr. Prout recommends the *pulvis ipecacuanhæ compositus*, which, he says, proves doubly useful—first, as a urinary astringent; and secondly, from its increasing the action of the skin; but probably the first effect is only a consequence of the second. The dose must depend upon circumstances; but from a quarter of a grain to two grains, two or three times a day, are the most effectual doses. If the Dover's powder, which is certainly the best preparation, be selected, from five grains to ten grains is the dose.

The effects of opium are the reduction of the urinary discharge. The cases recorded by Dr. Prout, and which occurred to Dr. Elliotson, and are also to be found in his work on Prussic Acid, clearly prove

the powerful effects of opium in reducing the urinary discharge. In these instances the medicine was given in very large doses. But the advantage of excessive doses seems very questionable. Every possible benefit is to be derived from moderate and well-regulated doses; for it must not be lost sight of that opium, like every other means, is only palliative, and cannot effect a radical or permanent cure.

Opium in its crude form is apt to affect the head, and in many aggravates the symptoms—the irritability, which it is given to relieve. It also produces constipation, and is in many ways objectionable in peculiar idiosyncrasies. In such instances the salts of morphia often answer very well; and I think seem, generally speaking, to be preferable to the other preparations of opium. Of the salts of morphia, the sulphate and hydrochlorate are the best; and either of these combined with ipecacuanha, as in the Dover's powder, forms a very valuable preparation, and can be given when the preparation with opium would disagree.

I have found the acetic extract of colchicum a useful combination, and also an extract of *nra ursi*: for instance, Mr. P——, whose case was mentioned before, after having been bled to twelve ounces, and had leeches applied to the loins, was directed to take one of the pills prescribed below *, night and morning; and as he complained of a feverish state and dryness of the mouth, a little citrate of ammonia with tincture of hyoscyamus was given twice a-day. I have, too, when the alvine functions have been sufficiently roused, prescribed kino and catechu, as before mentioned, in diabetic cases. This was the case with Mr. P. and I think with a great deal of benefit. In acute cases, we should always be cautious in prescribing opium before we have reduced the phlogistic state by blood-letting, in some of its modifications. Should opium in any form disagree, we must have recourse to other narcotics, and, though greatly inferior, hyoscyamus is next to opium; for which, however, it is to be understood there is no adequate substitute.

With the above, some tonic must be administered, and those which are both bracing and astringent seem best adapted. Iron, therefore, has been long used in such cases, the various preparations of which have each their advocates. Dr. Prout used to give full doses of the *ferri carbonas* (*ferri sesquioxidum*), made into an elec-

* R. Sulph. Potassæ, ℥ss.; Pulveris Ipecacuanhæ, gr. iv.; Sulph. Morphiæ, gr. ij. simul tere ut intime commisceantur deinde adde—

Extract. Colchic. Acet. gr. xv.; Ext. Uvæ Ursi, ℥ij. M. ft. massa in pilulas, No. xx. dividenda; sumat unam nocte maneque.

tuary with white of egg. But to derive the full advantage from iron, it should be given at the *minimum* of oxidation. Therefore the protocarbonate should be exhibited immediately it is precipitated by the process recommended in the Pharmacopœia. Dr. Prout states, that he has seen the very best effects produced by a combination of the compound powder of ipecacuanha and the carbonate, combined together in the form of electuary, in cases of a chronic character, attended with much debility and nervous irritation. As the patient improves, the narcotic should be reduced, and the tonic proportionally increased.

The difficulty of administering the protocarbonate (the efficient preparation of iron) induced me, some time since, to try some of the other salts; and from some statements of Dr. Sharpey, reporting very favourably of the phosphate of soda in diabetes, I imagined that a combination of the phosphoric acid with the oxide of iron might prove more effectual. The phosphate of iron may be readily formed by double decomposition—that is, by mixing together solutions of phosphate of soda and sulphate of iron: the phosphate of iron which is formed precipitates, and the sulphate of soda remains in solution. The ferruginous phosphate may be given in the same doses as the carbonate. I believe, however, that the sesquichloride, or rather the tincture of it, is as valuable and efficacious a preparation as any. We may begin with ten or fifteen minims three or four times a day, and which may be gradually increased to a drachm or more; with which a solution of morphia, or some fluid preparation of opium, may be usefully combined. I need scarcely observe, that the various other metallic tonics and astringents have been tried, but none have succeeded in effecting a radical cure. All that we can hope for is merely to keep the urgent symptoms in check.

The disulphate of quina has been much recommended in diabetes, where there is much debility; and, of course, as a very excellent tonic, would prove so far serviceable in diabetes. Various saline remedies, as the phosphate of soda, have been much recommended, and have been said even to have effected a cure. Whoever confides much, however, in any of these means, or expects a radical cure from them, will be, I fear, doomed to disappointment. Dr. Prout states, that out of twenty cases which had come under his observation during six or seven years, he met with but one instance in which the urine became perfectly natural; and in this it remained so but for a very short period. I myself, though I have very closely attended to all the cases of diabetes which

have come under my observation, never yet met with one in which the urine became perfectly natural, or even nearly approached to the natural state.

Tabes diuretica, or urinary emaciation of children.—There is a disease which attacks the urinary system of children, and which, I believe, has not attracted the notice it deserves. It is attended with considerable emaciation, and many anomalous phenomena, which render it of importance both in a pathological and therapeutical point of view. I brought it under the notice of the profession some years since, and I do not know that any one else has since mentioned it, with the exception of Dr. Willis. Children, from the age of six months and upwards to twelve or fourteen years, are most frequently the subjects. I believe many of the cases of atrophy which present to us, are of this character. In children of very tender years it is not probably much observed; but as they advance in age, the calls for passing water become urgent and irresistible. It often happens that the urine is voided during sleep, and the unfortunate patient is frequently blamed—often punished—very unjustly for a wilful crime. It should, however, be recollected, that this is a very harsh and a very unjust mode of proceeding, and as unreasonable as it would be to punish for the involuntary discharge of the urine and fæces in the coma of fever.

The first thing that attracts the notice of the attendants is, that the child begins to emaciate and look very ill; the features become sharpened; the nose pointed—or “peaked,” as they most usually term it; and the face assumes a pale, squalid, or sallow hue. The abdomen becomes tumid, and sometimes extremely prominent, and feels hard and tense to the touch. The appetite is variable, sometimes good, the child eating *heartily*, as the nurse describes it; sometimes indifferent, or even a loathing of food comes on; but, generally speaking, the appetite is not defective. But an insatiable thirst almost always attends; yet perhaps the patient does not absolutely call for drink when it is not in sight, but no sooner sees it than an irresistible craving for it impels to its use. In other cases, however, the thirst is urgent, and must be gratified: thus you will see children calling for drinks, and no sooner have they been indulged than their calls are renewed, and the attendants will tell you that “they do nothing but drink, drink, drink, all day long.” As the disease proceeds, a true marasmus supervenes; frequently the mesenteric glands become affected; or the rickets, or some other bad form of scrofula, shews itself. It is not my intention here to enter upon a lengthened

description of this disease, because, for a more detailed account I will refer you to my Essay on Diabetes. I shall, therefore, in this place merely enter generally upon the subject, and now lay before you the general characters and properties, and the mode of treatment.

The urine presents various characters, and perhaps the only invariable one is the inordinate quantity in which it is voided. The quantity, though always in excess, varies in different instances. I have known children, from two to four years of age, passing eight or ten pints of urine in the day. Sometimes it is of very low specific gravity, and yet contains urea in sufficient quantity to crystallize with nitric acid. It is then mostly pale coloured, and the crystals pearly. In many cases of this sort you will find the urine quite colourless and transparent; but on boiling, it becomes opalescent. It is possible to mistake this for chyle. I here present you with some urine of this description, passed by a child two years and a half old, a patient at the dispensary, and known to some of you. This child seems to be labouring under the disease now under consideration. When I heat this specimen, as you see, it becomes turbid, and hence you might suppose this to arise from the presence of albumen. But, as I have already explained, it arises from the presence of carbonate of lime, held in solution by excess of carbonic acid, and you will see that it will be rendered perfectly transparent again by a drop or two of the acetic, nitric, or hydrochloric acid,—as you see; and effervescence is produced by the escape of the carbonic acid. The cloudiness first arises from the heat expelling the excess of carbonic acid which held the carbonate of lime in solution. It is stated, that in *mollities ossium* the lime passes off with the urine, in combination with oxalic acid. I never could observe any thing of the kind in the turbid urine, sometimes resembling a mixture of chalk and water, and it seems to be rendered so by the mechanical suspension of phosphate or carbonate of lime, but more frequently the latter of these. In rickets, however, the carbonate seems to be held in solution by excess of carbonic acid.

In many cases there is a greenish tinge; this seems to be owing to the presence of bile reacted on by hydrochloric acid, and therefore is not indicative of the oxalate of lime diathesis. In other cases the urine is deeper coloured, of higher specific gravity, and contains considerably more than the natural proportion of urea. It is in such cases that the patient frequently passes the urine unconsciously during sleep, and, indeed, often is supposed to labour under incontinence of urine; nor can the patient, when once the call has

taken place, resist till a suitable opportunity occurs.

An almost invariable character is an excess of urea. When the quantity of urine is excessive, the excess of urea may not be indicated or sensible to the ordinary examination. It may then be necessary to concentrate a portion, and ascertain the quantity of crystals to be obtained from the concentrated urine: that is to say, we must estimate the absolute, not the relative, quantity of urea passed in a given time, and from this draw our conclusions. With a less quantity of urine the urea is readily crystallizable by the ordinary methods, but with a larger quantity of urine, the urea remaining the same, concentration may be necessary to effect the same result. For further details I would refer to the work already mentioned, and shall now proceed to state merely the treatment.

In the treatment of this disease it is as necessary to study how we may avoid mischief, as much as how we may do good. Many have resorted to urinary stimulants, as cantharides, turpentine, &c., and by such means have done much mischief. The first thing to be considered is the nature of the existing conditions, and the derangement of the functions, and our first means should be directed to the correction of these. Having bestowed the due degree of attention here, we have next to consider how we may reduce the inordinate quantity of urine, and correct its morbid conditions. There is no remedy known to me which has a greater influence in this respect than the preparations of iron; and of these the best suited are the protocarbonate of iron, the phosphate, and sesquichloride. I have tried all the other mineral tonics, but none seem equal to iron. It is not always easy to get children to take these remedies; the sesquichloride is nauseous; the protocarbonate and phosphate, as insoluble, must be given the form of electuary, to which some children are much averse. I have, in some such instances, substituted the potassio-tartrate of iron; and although this remedy possesses diuretic properties, I have not found this an objection. With the iron, opium, or its more active principle morphia, or some other narcotic, may be combined. *Ipecacuanha*, or some of its preparations, seems often a useful and efficient adjunct. When there is any thing like incontinence, perhaps we could not do a worse thing than exhibit turpentine, cantharides, &c. The *ura ursi* I have always found a much more suitable astringent. There are several vegetable remedies of a similar operation; such are the *Alchemilla arvensis*, *parcira*, *pyrola*, *colchicum*, &c. These, combined with narcotics, relieve the irritation of the

bladder and other portions of the urinary organs, upon which the diuresis in these cases very often depends. The extracts of the remedies above mentioned are astringent, indirectly so at least, by relieving the irritation upon which the diuresis depends. By way of a demulcent, and so far a means of relieving irritation, perhaps nothing is better than a combination of the *mistura amygdalæ* with the compound tincture of camphor. But, above all, let me advise you to attend carefully to the diseases of children, and to their differences; and perhaps the words of Hippocrates could not be more appropriately applied than upon the present occasion:—*Εἰ δὲ πολλὰ χλὺς οὐρείου, ἢ, τὶ τούτων προσγινοῖται, δείνον.*

We shall next proceed to *Calculi*.

NOTES OF

CLINICAL OBSERVATIONS ON FEVER.

BY CHAS. LENDRICK, M.D. T.C.D.

Queen's Professor of the Practice of Medicine in the School of Physic in Ireland, &c.

[Concluded from p. 108.]

Necessity for cleanliness—Means of insuring this—Prevention of excoriations—Methods of treating this where it occurs—Different kinds of poultice—Hydrostatic bed—Retention of urine—Necessity for catheterism, and mode of effecting it—Management of convalescence.

WANT of due attention to cleanliness during typhus fever exposes the patient to a double risk—that consequent on the irritation caused by discomfort and the foul odour around him aggravating the symptoms of his disease, and sufficient, in a case otherwise doubtful, to turn the scale against recovery—and that arising from the tendency of such a cause to produce cutaneous irritation, excoriation, and, ultimately, bed-sores. Nothing is more likely to contribute to the latter occurrence than the contact of filth, stale perspiration, or urine. The requisite precautions as to these matters cannot be entrusted with safety to ordinary nurses-tenders. So long as the patient is, as the phrase is, "notice taking," very gross negligence is not likely to occur; but when he becomes no longer conscious of the calls of nature, and the urine and fæces are discharged involuntarily, the arcana of the sick bed ought to be daily inspected by the physician in private practice, or by his clinical assistant in the hospital, so that the filthy concealments on the part of the nurse may not prove the means of marring the endeavours that he is making

for the patient's recovery. The body should be carefully cleansed, under superintendence, with a sponge and tepid water. The sponge is, however, often a mischievous instrument, and by its coarse use is likely to produce the very consequences it is intended to prevent—excoriation of the surface. Both it and the drying towel must be used in the most gentle mode, by pressing and withdrawing, and carefully avoiding any rubbing or sliding movement. Where the evacuations are discharged unconsciously by the patient, a piece of oiled silk, a yard square, ought to be stitched to the under sheet of the bed, and covered with half a dozen folds of linen. The latter should be removed after each evacuation, carefully cleaning the parts, and the oiled silk, as well as the sheets of the bed, changed daily. An open oiled silk bag, filled with a large sponge, ought to be placed under the orifice of the urethra, and removed as the sponge becomes soaked with urine. No compression or mode of restraining the urinary evacuation ought on any account to be had recourse to.

Stripping, or, in other words, excoriation, followed by ulceration and sloughing, is liable to occur not only as a consequence of blisters and other local stimulants resorted to for the purpose of rousing the dormant powers of life, especially where the sores are neglected, but also as the result of mere pressure and cutaneous irritation, acting on parts devoid of their usual vitality. Any degree of redness or lividity on the surface of the body ought, therefore, to be met by the simple precaution of causing the patient to lie off the affected part. If this precaution fail, we may rest assured that the preliminary symptoms of stripping are not undeserving attention. In such cases, the practice adopted at Mercer's Hospital is often successful—that of causing the patient to lie on soft flannel instead of linen, so as to absorb the stale perspiration. Should the use of the catheter be necessary, especial care is to be taken to avoid spilling the urine so as to come in contact with the skin.

The best preventive of stripping with which I am acquainted, is what is called by the druggists "spirit varnish," prepared, I believe, from gum sandarach. About the third part of its bulk of myrrh ought to be dissolved in it, and the varnish applied by means of a large soft camel-hair brush. It dries in a few minutes, so that three or four coats may be applied within a quarter of an hour. The patient may then use greater freedom with the part, which is not only protected by the coating of varnish, but receives from its ingredients a stimulus favourable for the prevention of sloughing. The so-

lution of nitrate of silver has been strongly recommended: it, however, in some cases irritates considerably, and rather favours than prevents the formation of bed-sores. It is often useful as an application (in the concentrated form) where the patient is violent and intractable, and where, other treatment being out of our power, a caustic eschar is likely to be a less evil than an irritated excoriation. Anxious as I am to prevent any breach of the skin, I never use the nitrate of silver as a mere preventive, nor do I think that it is possessed of any superiority over less precarious applications, except where used in the mode and under the circumstances I have mentioned. When excoriation has once taken place, the best plan is to keep the patient (if practicable) from lying on the part, and to dust it occasionally with the oxyde of zinc of the *Pharmacopœia*, which, if "prepared," is much superior to starch, &c. When this treatment fails, the excoriated surface ought to be covered with a piece of chamois leather double its size, and recently spread with soap plaster. The margin of this plaster is to be covered by an adhering cushion, formed of flat annular layers of adhesive plaster, including a strip of lint between the layers. Thus the pressure is kept from the surface of the excoriation itself. After ulceration has occurred, the best dressing is a piece of lint dipped in warm port-wine. It ought to be covered with an annular plaster-cushion, as just described, and a circular piece of plaster laid over all. The latter may be raised daily, so as to permit the port-wine dressing to be changed.

Poultices can never be applied with advantage where the patient is obliged to lie on the excoriated or ulcerated surface. Where the sores are so extensive that the patient must lie on some diseased part, that on which he lies ought to be treated in the way just described, and a poultice applied on the parts that are not compressed; since, to apply a poultice to the under surface is, in fact, to cause the patient to lie on a mere poultice-cloth—by no means a soothing application. Three ounces of sifted oatmeal, and one ounce of fine linsed meal, will make a poultice six inches broad. The meal ought to be rubbed with rather less than double its quantity of cold water, and it may be boiled to the requisite consistence in about five minutes. The turnip and carrot poultices are best made by substituting for a part of the meal the pulp of boiled turnips, or of the red part of carrots, previously rubbed through a sieve. The charcoal poultice is a filthy application, and owes its reputation more to theory than experience: if used, it ought to be made from the "prepared" charcoal of the *Pharmacopœia*. These directions are indispensable, as grit-

tiness or shreds in a poultice cause it to do more harm than good. Indeed, every thing connected with poulticing, whether as to the preparation or mode of application, requires accurate superintendence, and the readiness of contrivance only to be acquired by hospital or private practice. Pupils who neglect the opportunities afforded to them for this purpose at Sir Patrick Dun's and Mercer's Hospitals are left without excuse for their ignorance.

Port-wine and water, porter, or wort, in the process of fermentation with yeast, are frequently used in sloughing cases, to form the poultice, instead of water. With the same object, it is generally the practice to apply, between it and the slough, a piece of lint dipped in elemi and turpentine, Peruvian balsam, port-wine, dilute solution of the chloride of soda, or solution of morphine; according to the character of the ulcer as to sloughing, fetor, or irritability. The practice in such cases must often be empirical, one remedy succeeding when another of higher reputation has failed. After the slough has separated, the best dressing is dry lint, provided the sloughing process seems to have terminated, and that the surface of the ulcer is clean and disposed to granulate. The lint must be allowed to detach spontaneously, and on no account be forcibly separated. I have succeeded in treating excruciating blister-sores, which had resisted every other application, by means of pledgets of lint dipped in an opiate solution, and allowed to adhere for a month or more, the edges being clipped as they became detached. This mode of treatment is nearly that of burns, by means of cotton wadding—a plan that often answers extremely well with bed sores. In some cases, however, all other modes of treatment fail, and, in order to save the patient, we must have recourse to the hydrostatic bed. Not only bed-sores, but also numerous cases of sloughing erysipelas, extensive burns, and gangrene consequent on injuries of the spine, have been successfully treated by means of this apparatus, at Mercer's Hospital, and which I firmly believe would have otherwise proved fatal—drawing my inference from the termination of similar instances of disease or injury. This single invention would, indeed, entitle Dr. Arnott to the name of a benefactor of the human race.

The principle of the hydrostatic bed is to enable the weight of the body, which must be supported by some means, to be diffused over an extensive surface, with, of course, a corresponding diminution of pressure within any given space. Soft beds become hard by the continued pressure on their soft material; and air-cushions, by the compression of their air,

are converted into tense surfaces; thus they often do more harm than a hair mattress. The peculiarity of the water-bed is, that the patient rests on a loose cloth, the water rising to a certain height only. If the cloth were tense, the apparatus would be as useless as the air-cushion. The sinking produced in the latter by the compression of air, takes place in the hydrostatic bed by the displacement, to a certain extent, of the free and incompressible fluid; the cloth not in any way supporting the weight, but merely preventing the body from being wetted, and permitting it to float, with a pressure slight in proportion to the extent of the surface below the level of the water. By the experiment I shew to the class, it appears that the pressure, even on the under surface of the body, is scarcely greater than that of an ordinary poultice or a surgical dressing-bandage; so that the entire surface above and below is placed under almost equally advantageous circumstances as to the chance for the completion of a healing process.

Hydrostatic beds are at present regularly constructed by artificers. In remote districts, one can easily be contrived by means of a large tub, and the India-rubber cloth now so readily procured. For the reasons already stated, the cloth must be large, so as to lie loosely and in folds over the surface of the water; its edges being merely tacked to the tub, to prevent them from falling into it. Several folds of soft blanket should be placed under the body. This is better than the mattress generally used, and prevents the patient from being incommoded by heat or cold, for these opposite sensations are often complained of. The annoyance of the sinking of the parts of the body near the shoulders is removed by placing an air-cushion or a pillow-case, filled with blown bladders, under the blanket. This diminishes the specific gravity of the weight immediately superincumbent, and the patient may thus be raised nearly to a sitting posture, if desirable. The air-cushion does not act here as on a common bed, by the tenseness of its surface, the included air being very slightly compressed, on account of the yielding nature of its fluid substratum; thus the pressure on the patient's body is only equal to that on the cushion by the water. Patients often feel relief from occasionally being removed to a common bed. The better way is to alternate the mode of rest; having recourse to the hydrostatic bed on the aggravation of the ulcerative process, and removing the patient to a common bed, if desired by him, on its amendment to a certain degree.

Bed-sores occur in many cases besides those of fever; wherever, indeed, the pa-

tient is bed-ridden, and the local circulation and nervous energy are deficient; especially if emaciation be present. The same remark applies to retention of urine, the last subject for consideration among the three specified in page 108.

Retention of urine, or *Ischuria vesicalis*, as it is termed by Cullen, attends on several diseases, and is often a primary affection. Symptoms resembling those of typhus fever, or of apoplexy itself, are produced occasionally in persons otherwise healthy by such retention merely. Hence it may be inferred, that the danger of a patient already labouring under one of those diseases, must be aggravated in no slight degree by the supervention of an occurrence in itself capable of producing consequences similar to those under which he suffers. Medical practitioners would, indeed, be much seldomer caught napping, if it were made a rule to examine the urine daily passed, throughout the entire period of fever and other diseases. Thus suspicion would be excited in time; for it is to the want of suspicion at all, and not to mistake about the matter suspected, that such errors are generally to be attributed. I have found nearly half a gallon of urine, after death, in the bladder of a fever patient, where retention had never been even suspected, and where the nurse "reported" most favourably as to that evacuation. Almost that quantity has been drawn off by the catheter, in the living patient, where both he and the nurse insisted that the urine was regularly passed. Whenever, indeed, it is said that the urine is "very often" discharged, the great probability is, that the cistern is overflowing. In short, much mischief and loss of professional reputation may be avoided, by insisting on all the urine that can be procured being kept for inspection, so as to be aware, from the diminution of the usual quantity, that retention is likely to occur; and also, by daily examining the state of the bladder. This examination is not a difficult matter. When the bladder is distended it forms a tumor, which, as it rises mesially, and immediately above and from behind the os pubis, can scarcely be confounded with any other. In corpulent persons the distended state of the bladder can in general be detected by the dull sound just above the pubis, as compared with that over the rest of the abdomen, on percussion being made by striking the fingers laid on its surface. As I have already remarked, however, the great thing is to suspect the existence of retention of urine, as, in a doubtful case, it is better to introduce the catheter unnecessarily, than to delay its use when requisite.

Dexterity in the use of the female

catheter is generally considered indispensable in the physician-accoucheur; and a knowledge of the mode of introducing the male instrument is equally necessary to the medical attendant, during fever and other diseases, in which retention of urine frequently occurs. Moderate attention to the opportunities which almost every pupil possesses at the present day, will enable him to afford relief in the great proportion of cases, without doing injury or increasing the difficulties in the rest. A flexible catheter, of the size about No. 5, curved by keeping it on the wire, is the best for general use. It ought to be of the very best quality, as, if devoid of proper firmness and elasticity, it is with difficulty made to slide along the upper surface of the urethra, where it passes under the pubis—a manœuvre in the gentle accomplishment of which the distinction between dexterous and awkward catheterism in ordinary cases generally consists. Authors dwell, and very justly, on the importance of acquiring the tact of judging whether the instrument is bending or advancing; also of not pressing it against any obstacle, but of waiting for spasmodic resistance to subside; and of changing the direction of the point so as to avoid the sinuosities of the passage, and the elastic impediments they occasion. To these rules may be added that of preserving the concavity of the instrument upwards (in the anatomical sense of the word), and of preventing the inclination it often has to turn in a lateral direction.

By watching a mark placed on the handle of the instrument corresponding to its concavity, and by keeping this upwards on renewing the attempt, such an occurrence may be rectified. Sometimes it is easier to introduce the silver male catheter than the flexible. Like the other, it must be held very loosely, and almost allowed to find its own way, sliding along the upper and convex surface of the urethra, without hitching on it. All the difficulties of ordinary catheterism, and the mode of surmounting them, can be learned on the dead body, with the exception of spasm, which is to be overcome, merely by not resisting it. The operation on the female can also be learned, and perhaps still better than the other, on the dead subject, the eyes of the operator being closed. The same gentleness and feeling of the way is requisite, as in the case of the male urethra, and the flexible is the better instrument.

Where, in fever or any other disease, retention of urine is attributable to mere debility, and no symptoms of excitement are present, there ought not to be any hesitation as to immediately drawing off the fluid as soon as its accumulation is

ascertained, and that an enema and fomentation to the pubis have failed in procuring an evacuation. If the operation prove difficult, it ought to be recollected that persons suffering from organic disease of the urethra are as liable as others to fever, and the diseases in which retention usually occurs. This consideration ought to make the operator careful not to convert, by perseverance in ineffectual efforts at catheterism, a difficult case into an unmanageable one. Even where the result of investigation shews that the patient is free from stricture, &c. the delay of an hour, by allowing the irritation caused by the previous attempt to subside, will render the operation much easier, either in the same or other hands.

If the power of evacuation does not return after the introduction of the catheter, it will, in the average of cases, be necessary to draw the urine off twice daily. Sometimes the bladder refills so slowly that once may be sufficient. On the other hand, the secretion is occasionally so rapid, that the catheter must be introduced thrice, or oftener. This necessity is, however, to be judged of by the state of the bladder, and not by the patient's sensations, as sometimes the irritation of the instrument causes, on its withdrawal, a *nisus*, resembling a call to discharge the urine, and which, it is obvious, ought not to afford grounds for repeating the operation. Where it is necessary to draw off the urine frequently, or where the operation is difficult, or attended by much irritation, it may be preferable to keep the catheter in the bladder till the power of evacuating the urine returns, especially if it do not thus prove a source of irritation, and if frequent recourse to professional assistance be inconvenient. For this purpose the flexible catheter should be retained by means of a lincn compress on the perineum, covered by a T, or rather X bandage, so as to admit of the fæcal evacuation being performed. The end of the tube (plugged) is to be tied to the girdle of the bandage, and (if the patient be a male) the penis is to be kept in the same position by means of a strip of linen properly pinned. This is one of the best contrivances I know of, and the least likely to cause irritation. If it do so, the catheter must be withdrawn, and introduced as required.

Retention of urine sometimes, however, exists in what is called *sthenic* form, with excitement, spasm, or inflammation, as an attendant on the inflammatory forms of fever, abdominal inflammation, hemorrhoids; and often as a primary affection. The diagnosis of such cases is by far more difficult at the bed side than books represent; and it is often a very nice matter

to distinguish, whether the retention of urine has produced the symptoms of local and constitutional distress; or whether these are primary in their nature, and the source of the retention. Where there is not any reason to suspect the existence of stricture, and that the sufferings of the patient are recent, proportional to the increased distension of the bladder, and rather permanent than characterised by paroxysms of pain and spasm, there is reason to suppose that the former is the case. If, on the other hand, the patient labours under stricture, or the previous symptoms induce a suspicion as to its existence; if the spasmodic paroxysms are violent, and if they took place before the bladder became much distended, there is good reason to suppose that the retention depends on causes not likely to be subdued by an attempt to introduce the catheter, unless with the precedence of soothing measures; and that the attempt, however gently made, without such precautions will be more likely to prolong than relieve the patient's sufferings. Instead, therefore, of trying the catheter at once, which is the most obvious mode of relief in the first-mentioned class of cases, I recommend an accurate investigation of the circumstances aforementioned; and in the second variety, to have recourse to soothing measures to an extent proportional to the development of its characters, especially if instruments have already been tried in vain. These measures are, a large enema of warm water, followed by a small one containing opium; venesection, if decided inflammatory symptoms have preceded the retention; fomentations to the pubis and perineum; leeches to the latter; the semicupium (formed of a common tub); castor oil, followed on its operation by a dose of opium; tincture of muriate of iron, twenty drops every half hour; and the total immersion of the body in the hot bath. The measures first mentioned require but little time for their application and effect; and as the delay of an hour can scarcely do harm, they may be had recourse to in almost every doubtful case, as rendering the success of catheterism more probable, and perhaps preventing the necessity for it at all. Where a patient obtains relief without the use of instruments, the urine is not in general discharged at once, but oozes from time to time. This oozing is not to be confounded with the overflowing of a distended and paralyzed bladder. The discharge in the former is, to a certain extent, under the patient's command, is followed by relief, and the bladder is found to become smaller and softer; whereas, in the stillacidium urinæ, the bladder retains its state, the evacuation is

almost or altogether involuntary, and the sufferings of the patient remain unabated, if he does not become comatose or delirious.

When a patient has become convalescent from fever, the difficulties of his medical attendant are often greater than before; as alarm being now over, the requisite directions are submitted to with greater hesitation. It, indeed, not unfrequently happens, that all the ground gained by judicious treatment is lost at this time, and life along with it, by imprudence on the part of the patient or his friends. In hospital practice, the restorative dietary is usually divided into what is termed the "convalescent," from which animal preparations are excluded—the "middle," which includes light broth—and the "full," consisting partly of solid animal food. A similar gradation should be pursued in private practice, preserving the same simplicity of nourishment, and avoiding complex articles. Well-made flummery or baked apples, chicken-broth, and boiled chicken, with a moderate allowance of wine and water, may constitute this gradation; and it is well to confine the patient to this simple dietary, till his capability of digesting and assimilating nutriment without unduly stimulating the system has been determined*. As a relapse is always to be dreaded more than the original disease, the patient's appetite is not only to be restrained, but, on the occurrence of any foulness of the tongue, headache, shivering, or other symptoms which usually usher in fever, he ought at once to be restricted to low diet, and confinement to bed. Should the symptoms continue, a gentle emetic ought to be administered, and the treatment requisite at the commencement of fever had recourse to.

I have already remarked, that the accessory causes of fever are in themselves inadequate to its production, although they powerfully aid contagion or pestilential agency (which are to typhus fever what an external injury is to constitutional irritation), in rendering the patient more susceptible of their influence, as well as in modifying the type of the future disease, or superadding organic affections. Thus cold, fatigue, &c. will cause a patient to be attacked by typhus fever, who might otherwise have escaped the effects of contagion; and as exposure to the vicissitudes of weather is in itself liable to cause inflammation of the respiratory organs, so when, in addition to this, the peculiar causes of typhus fever are in opera-

* A more liberal allowance of nourishment is of course requisite in sloughing cases, together with bark, &c.

tion, we find pneumonia, &c. combined with typhus, especially in those already predisposed to pulmonary affections.

The existence of contagion* is at last almost universally admitted; and from what has been remarked in the foregoing observations, it must be obvious that the plan generally recommended (but not generally acted on), of avoiding exposure to both the peculiar and accessory causes of fever, is indispensable for safety. Persons exposed to contagion ought to avoid cold, fatigue, mental anxiety, &c. as much as possible; and reciprocally, those who are already exposed to the influence of cold, &c. or any bodily indisposition, ought to avoid undue exposure to contagion. It is certainly the duty of the medical man to undergo any risk that is necessary for its performance, but not to go further; and therefore exposure to contagion should be as little, and for as short a time, as is practicable consistently therewith. The patient's breath ought to be carefully avoided; and whenever it is necessary to examine the surface of the body, the clothes should be previously thrown back for a short time, so as to allow the first and most noxious effluvia to escape. Stethoscopic examinations are useful in a much less proportion of cases than pupils suppose. Where there is any respiratory affection, percussion may be advantageously substituted; for, till some dulness of sound is perceptible, stethoscopia is generally unnecessary as accessory to treatment, inasmuch as a concurrence of the signs of pulmonary inflammation are requisite, before bleeding, tartarized antimony, or mercurialism, would be justifiable, where typhus fever is present. The stethoscope ought to be fourteen or fifteen inches long. With such an instrument I can hear the morbid sounds in the chest as well as with a shorter. Some persons, however, cannot be satisfied without nuzzling among the sources of infection.

The preceding observations on fever have been written from the notes of my clinical lectures at Sir Patrick Dun's Hospital, not only according to the sense but the words, as far as I can recollect; and at the request of some of my pupils there and at Mercer's Hospital, who wished that they might be rendered more available for their instruction than as mere oral, and occasionally unconnected remarks†. I have not dwelt on post-mortem appearances, which shew the effects of diseases occasionally coexisting rather than the

effects, and still less the cause or essence of fever itself. As, after the constitutional irritation produced by external injury, so, after the typhoid disease consequent on contagion and pestilential agency, where organic disease has been called into operation, almost every variety of organic change is discoverable on dissection, and as such changes do not usually present any marked difference from the results of similar diseases when unconnected with fever, the notice of them appropriately belongs to another occasion. It is the principal opprobrium of medical science, that its votaries generally seem determined to follow up the investigation of one of the sources of disease to the disregard of the rest, as if the site of disease were to be found for a time in the solids, for a time in the fluids, and then in the untangible vital principle itself, instead of being referable to a morbid change always existing in the latter, and occasionally in the two former. The consequence of the exclusive mode of investigation has been, that nine-tenths of the results of the talent and industry expended on it have actually gone for nothing. I therefore recommend my pupils not to be led away by amusing speculations while engaged in pursuits so arduous and occupative of time as the medical; but to clear away the rubbish from their path, by dismissing every consideration which does not afford at least presumptive proof that the investigation, if followed up, may be rendered available for practical purposes.

PHYSIOLOGICAL PROBLEM.

By WILLIAM GRIFFIN, M.D. Limerick.

Does suffering necessarily imply consciousness? Are sentient beings necessarily percipient?

NO. IV.

If it were impossible for me to offer the slightest explanation of the opinion that sensation (by which I mean feeling, in the popular sense of the term), is different from, and may exist independent of perception, consciousness, or knowledge—if the division of a sentient being into two separate independent existences was as inconceivable as the division of a conscious or percipient one, I should scarcely believe myself the less bound to admit the clear inferences deducible from the extraordinary facts stated in the course of this inquiry. It has been incontrovertibly

* See Dublin Medical Journal, Jan. 1836, page 418.

† For the sake of brevity I have not specified the cases.

determined that perception, thought, memory, consciousness, and the intellectual functions, are connected with the cerebral lobes, and disappear with their removal. Yet after their removal, and when no parts are left above the corpora quadrigemina, and in amphibia and cold-blooded animals even after decapitation, signs of sensation and suffering, and even spontaneous actions, are observed to take place, to doubt the reality and dependence of which would be to discredit the instincts and intuitions which make part of our very nature.

I cannot but think that sufficient has been already said to convince the reader, if not of the absolute existence of the distinctions proposed between sensation and perception, at least of those distinctions being conceivable. That they are so I can give no stronger proof than is offered by Reid, in his metaphysical speculations on the subject. "If nature," he says, "had given us nothing more than impressions made on the body, and sensations in our minds corresponding to them, we should in that case have been merely sentient, but not percipient beings. We should never have been able to form a conception of any external object, far less a belief of its existence. Our sensations have no resemblance to external objects; nor can we discover by our reason any necessary connexion between the existence of the former and that of the latter. We might perhaps have been made of such a constitution as to have our present perceptions connected with other sensations. We might, perhaps, have had the perception of external objects, without either impressions upon the organs of sense or sensation. Or, lastly, the perceptions we have might have been immediately connected with the impressions upon our organs without any intervention of sensations. This last seems really to be the case in one instance—to wit, in our perception of the visible figure of bodies."

It did not occur to Reid how truly he was depicting the character of a large class of animals in these speculations of what he conceived as merely possible. The animal creation may perhaps be properly considered as including three classes of organized beings. Those with insentient or ganglionic nerves only, and whose organs perform their functions without feeling or conscious-

ness on the part of the individuals, as the heart and bowels do in man—if, indeed, any such simple organizations exist even in the lowest type of animals.

Those, again, described as possible forms of existence by Reid—the pure sentient organizations—animals possessed of a spinal cord, evincing obvious signs of sensation, and displaying actions evidently resulting from and dependent on such sensation—animals possessing appetites and instincts, and apparently sensible to pleasure and to pain—animals whose lives are but chains of momentary feelings, successive but independent of one another, who, possessing no faculty of perception or memory, have no consciousness either of their own existence, or of the existence of the world about them, and who, having a simple organization, throughout which a single sense is equally diffused, admit of being multiplied by division into more numerous existences.

And, finally, those to whose spinal cord a brain is superadded, to whose sentient existence a percipient and conscious one is attached, whose life is not made up, as in the sentient being, of a thousand separate existences—a thousand transitory sensations, which, though succeeding each other in one organization, come into being and die without any absolute relation; but is impressed with a sense of continuity and individuality by new and extraordinary faculties, which perceive and detain and record every fleeting sensation, and which can recal, and examine, and compare, and dismiss them at pleasure. It may be said, indeed, that the life even of a mere sentient being has a sort of continuity; the series of sensations of which it is made up are connected; it can hardly be called related, by its organization; and there is no period, however short, while that organization holds perfect, in which sensations are not experienced. But it is an animal living always strictly in the present, no moment of its existence having a conscious relation with the past or future, any more than if each single one belonged to a distinct and different individual. The life of the animal with brain, on the other hand—of the perceptive conscious animal, is connected from its earliest to its latest period, in all its pains and pleasures, by a memory which recalls them

at a moment, and an intuitive conviction that they have been experienced by the same single being which recalls them.

In this view it may be said, that in all the higher classes of animals, the organization is made up of three distinct forms or types of existence, each wholly independent of that which has succeeded or is superadded to it. It is no slight proof of the truth of this hypothesis, if such it may be called, that the independence of these three distinct modes of life may be illustrated by actual analysis, as Magendie, Fleurens, and Bouillaud, have shewn; that the percipient organ may be destroyed, leaving the sentient and ganglionic organization uninjured, and the sentient may be destroyed, leaving the insentient or purely vital functions actively proceeding; that, in fact, as an animal is built up, so may we contrive carefully to unbuild him again.

Take away, for instance, the anterior lobes of the brain, or let them be compressed or rendered useless by an apoplectic attack, and the conscious percipient portions of the being are extinguished, while the purely sentient and organic remain. This may, perhaps, be held as mere assumption with regard to the apoplectic; since, if signs of sensation are evinced, there are grounds for supposing that some degree of consciousness remains: but in the case of ablation of the brain, or of the brain never having been formed, as in the animals experimented on by MM. Magendie and Desmoulins, in the acephalous fœtus, there can be no doubt as to the absence of consciousness, unless we doubt that the brain is the organ upon which that faculty is dependent. Yet signs, apparently the most indisputable, of the persistence of sensation, are freely displayed. "When, after having opened the cranium, all the parts of the cerebrum, the optic lobes, and the entire cerebellum, are cut away, the animal continues sensible to all the impressions which have their seat in the face, excepting that of sight. It continues to be as vividly affected by sounds, odours, sapid substances, and punctures of the face, as if it experienced no other inconvenience than that which results from the mere loss of blood. It cries if a hair of its whisker be plucked, or if a strong acid be applied to the nose, and endeavours, with the paws, to remove

any source of irritation, as it would do if it had not been mutilated *."

It may be naturally asked, when the phenomena so generally attributed to perception and volition are so strikingly exhibited in animals mutilated in the manner described, why we should deny them these faculties, or look upon them as no longer conscious but sentient beings? Such a question may, perhaps, be most aptly answered by another. Supposing the definitions of perception and volition, of sensation and sentient action, already offered, to be correct, what phenomena should we expect to disappear on removal of the conscious or percipient organ? The animal should lose its memory, its powers of association, its recognition of objects, its knowledge of or connexion with an external world, its incentives to actions. If it felt hunger, or thirst, or cold, it would lie still and suffer, having no perception either of its wants or the means of relieving them. It would hence remain inert, and as if in profound stupor, unless excited by the stimulus of physical agents in contact with it, or by such causes as usually call up instinctive muscular movements. It would, on stimulation, display all such actions as are most closely linked with pure sensations or instincts; the amount or extent of such actions being very much determined by the amount or degree in which the conditions essential to the performance of the functions of the spinal cord are interfered with in each particular animal, by the mutilation or decapitation. In the cold-blooded animals, we know them to be interfered with very little, and in the earthworm and polypus, which have no brain, and in whom instincts stand in the place of perceptions and volitions, still less.

Let us now compare these supposed results with those which have been found actually to take place on ablation of the brain in animals which have survived the operation. I cannot refer to a more striking or satisfactory experiment than that of M. Fleurens on the chicken, already mentioned, which lived ten months in perfect health, after the operation.

"He had scarcely removed the two cerebral lobes before the sight of both eyes was suddenly lost; the hearing

* *Anat. des Syst. Nerv.* p. 560.

was also gone, and the animal did not give the slightest sign of volition, but kept himself perfectly upright upon his legs, and walked when he was irritated or when he was pushed; when thrown into the air he flew, and swallowed water when it was poured into his beak.

"He never moved unless when irritated; when placed upon his feet he remained upon them; when resting on his belly, in the manner chickens rest when asleep, he appeared plunged in a sort of drowsiness, which neither sound nor light in the slightest degree disturbed. Nothing but direct irritation, such as pinching, or pricking, or striking, had any effect in rousing him.

"When the animal did move about, it seemed to do so without any motive or object, though there were no convulsions nor any want of harmony in its movements; if it met with any obstruction, it did not know how to avoid it.

"The chicken was quite healthy, and, five months after the operation, the wound had quite healed, and a new layer of bony matter was forming.

"Still it had no sense of smell or taste; neither had it any sensation of hunger or thirst; for, after allowing it to fast for three whole days, and then placing food immediately under its nostrils, and afterwards putting it into his beak and putting its beak into water, it did not shew the slightest disposition to eat or drink; and would have died for want of nourishment, if it had not been fed by force.

"It seemed entirely to have lost its memory; for if it struck against any body it would not avoid it, but repeat the blow immediately."

M. Fleurens, Dr. Marshall Hall, and Mr. Grainger, are of opinion that this chicken, during the long period of ten months which it has survived the operation, never experienced one single sensation or perception—that it was wholly insensient, and all its movements automatic; yet it walked and flew, and swallowed and drank, upon occasion, and aroused itself from its usual stupor when pinched, pricked, or beaten.

Looking upon the animal, however, as having retained common sensation, how perfectly explicable are all the phenomena detailed; how strictly they accord with those which might be naturally anticipated from the mutilation.

Sight and hearing were lost. These functions, though perhaps like common

sensation dependent on the spinal cord, are to any useful purpose essentially associated with the perceptive faculty, and incapable of being effectively exercised without it. It does not at all follow, because sensation is presumed to be distinct and independent of perception, that all the peculiar senses were calculated to be of use, or intended for existence independent of it. For almost all useful purposes of the sense of sight, and perhaps of smell and of hearing, perception is as essential as memory.

There is so much of experience and rational induction required in all the perceptions by these senses which we can turn to any useful account, that the impressions they convey disconnected with such inductions tend to no end. Hence it may perhaps be considered as a universal fact, that all animals possessing special senses, such as man possesses, must also have a percipient organ or brain. This I believe will be found to be the case with respect to all animals possessing the sense of sight, the most intellectual of the senses; and of this we may be at all events assured, that if any animals without brain possess organs of sight, they can only derive from them the mere sensation of light.

The chicken did not shew the slightest sign of volition (spontaneous motion), and never moved unless when irritated. As a purely sentient animal, so rendered by the removal of its percipient organ, it would of course evince no volition; but it was so far inferior to a much lower order of beings—those which were created purely sentient—that it had not, in the absence of a percipient organ, the sentient instincts which in such animals supply the want of motives and volitions; nor could its sensations so readily take the place of volitions, and spontaneously suggest or occasion movements, unless aroused to action by external irritation.

When it did move about, it seemed to do so without motive or object; as if it met with any obstruction, did not know how to avoid it. Here, again, we see the disadvantage the chicken laboured under in not having been created without brain; for if it had, all, even the least, of its sensations would have led to the necessary results as instinctively as those painful feelings did which made it walk when struck, and fly when thrown into the air, and swallow when food was put down its throat.

It had lost the perception and memory which heretofore enabled it to avoid obstacles, and was gifted with no sentient instinct that could answer as a substitute.

It neither hungered nor thirsted. This perhaps is very doubtful. Hunger and thirst are pure sensations, not necessarily connected with cerebral perceptions in any way, and capable of being as universally diffused as common sensation throughout the entire frame, if nature had so pleased it. One should not, therefore, at once anticipate the loss of such sensations on ablation of the brain, though it is probable, in the higher classes of animals, that these as well as other peculiar sensations having their seat so high up in the spinal cord, are wholly extinguished by decapitation. If the chicken both hungered and thirsted, I think the observable phenomena would have been still the same. Having lost its memory, and, with it, its perceptions—its associations—in short, all its knowledge or consciousness of an external world—food might be placed under its nostrils or in its beak, and its beak into water, and yet it would evince no greater disposition to eat or drink than if a piece of iron was offered to it for refection. It may be, and I question whether it is not, the case, that in animals created without brain, the simple sensations involve immediately in themselves some obscure feelings of external existences; but such intuitive or instinctive feelings must be wholly superfluous in animals created with a perceptive organ whose appetites were to be supplied through its instrumentality; and hence it is, such animals fall below the merest sentient being when deprived of that organ.

The acephalous infant furnishes us with an illustration of a purely sentient existence, still more satisfactory than that of M. Fleurens' chicken. Headless infants, or at least infants possessing merely the basis of the skull and face, and devoid of the brain, have been known to live for some days after birth. In these cases, sucking, deglutition, respiration, and the expulsion of the urine and feces, were performed as in the perfect state, *cries were also uttered*, and the motions of the limbs usual with infants after birth took place. Such motions, however, after a little time occurred only on excitation by some external agent. Are we to believe,

that there was nothing whatsoever of sensation or human feeling in the phenomena displayed during the short lives of these little beings?

Mr. Travers mentions a case in which the *os frontis* was driven in by a fall, and a considerable portion of the brain extruded at the wound of the scalp; yet the boy, "although utterly deprived of consciousness, made obvious but unavailing efforts to aid the surgeon in getting him into bed, and thrust his arm mechanically into the sleeve of a clean shirt, after his hand had been placed in the opening of the sleeve."

If we can implicitly admit the correctness of Mr. Travers' opinion in this case, that there was an utter absence of consciousness, as I presume we may, the phenomena are quite inexplicable on any other hypothesis but that which assumes the integrity of the sentient system after the destruction of the conscious or percipient. The motions performed, it will be observed were neither voluntary, that is, designed, nor instinctive, as the actions of sucking or yawning. They were the result of trained associations, that is, of actions artificially associated with particular sensations. Mere impressions may possibly excite certain combined actions, the connexion being established from the first in the organization; but no connexion can be conceived between arbitrary actions—actions arising out of, and associated with our perceptions or sensations, and mere impressions.

These are all instances of purely sentient life persisting after ablation of the percipient or cerebral life. But if the spinal cord—the organ upon which all sensation in living beings would seem to be dependent, was destroyed as well as the brain, in the gradual manner adopted in Dr. W. Philip's experiments, we find a lower grade of life, the organic, yet remaining—we find the heart and vessels of circulation persisting in their functions, and even the secretions going on for a period. Sensation is now utterly extinct. Muscles may contract on stimulation as long as their irritability lasts, but there are no longer evinced any regular or associated movements, any expressions of suffering, or phenomena indicative of design, any spontaneity of action. This last and lowest organization forming the basis on which the sentient and percipient systems are erected in

the higher orders of animals may perhaps be itself like each of these, the type of an immense class; yet there are too many strong analogies in favour of the more popular notion, that feeling characterizes even the lowest forms of animal existence, to permit our coming to any decided conclusion on the subject.

In this manner, by removing the superstructures successively, we may unbuild the frame of the perfect animal, so as eventually to reduce it to the simplest organization—the lowest of living forms. But we have other very striking evidences, that the organic, sentient, and percipient forms of life, are essentially distinct, in the discoveries of Tiedemann and others respecting the development of the fœtus. Tiedemann has shewn that in the earliest period of fœtal life, the brain and spinal cord do not exist, while the organic functions are in active operation. At the end of the second month the spinal cord and two anterior prolongations or peduncles of the brain are formed, or in other words the sentient existence is established. Finally, the cerebral lobes become gradually developed, and the organization essential to thought and memory and consciousness is achieved*.

It is singularly illustrative of the distinctions here pointed out, that they are as observable in the dying animal as in the process of its formation. Each form of life dies, too, precisely in the order one might anticipate from its known dependencies. The organic, the first formed, and the basis upon which sensations and perception subsist, necessarily lives longest; while the percipient system, the last added, and the least essential to existence, dies earliest. It is extinguished, indeed, temporarily in very slight disturbances of the organic or sentient functions—in common faint-

ing, in apoplexy, and in epileptic fits; and even in profound sleep we are as wholly unconscious of existence as if the percipient organ was removed; and in dying, the loss of mental consciousness always precedes insensibility, though sometimes perhaps only for a very short period. The time for which the sentient life may persist after the loss of the percipient is very uncertain, though generally very inconsiderable in the higher classes of animals, and differing much in the warm, in the cold-blooded, and in the amphibiæ. The diseases of the human frame furnish us with numerous instances of the continuance of sentient life, in cases where we could have no doubt there was a suspension of all consciousness—an extinction, for the time, of knowledge, thought, and memory, and even when perfect death is impending, and sensation itself has expired throughout the rest of the system, it still clings to the respiratory function—the last and most important with which it is connected.

I very much doubt whether the fœtus in utero at any period, or even the infant of a few hours old, is a percipient being—that is, a being exercising its percipient organ; nor, if I am correct in my conclusions, can there be a more beautiful example of pure sentient existence than the latter presents as it rests or sleeps for the first time in the lap of its nurse. Never having, as I presume, yet experienced a distinct perception—a sensation referred to the external cause which produced it—it cannot have thought, or knowledge, or belief, or memory, of any thing. It feels and moves; it withdraws its hand if touched, it turns, or throws its arm outside the clothes, or draws up its little knees, and seeks an easier position to lie in: but it refers no sensation to a self that felt that or other sensations before. It has perhaps a constant sense of existence, such as may possibly be inseparable from sensation; arising not from any knowledge or belief or thought about itself as distinct from an external world, nor from any reference of that sense to a thinking being which experiences it; but from whatever instinctive feeling of individuality may be imparted by a constant succession of sensations in one organization. All men during profound sleep are, in fact, like the acephalous or the new-born infant; but mere sentient beings, and the many successive sen-

* "It is a singular but beautiful physiological fact, that living organizations generally should be developed and called into being, should obey the same laws and rules of development, should become more complex and perfect in the same gradual manner in which man individually, from the first germ of his existence to his perfect form, exhibits; that the animal kingdom, from its minutest microscopic point of vital endowment, should pursue an analogous perfection of development of different organs, should exhibit the same systems mutually dependent or rising into or out of each other, that are called into operation in rapid succession during the short nine months of human embryonic and fœtal existence; that we ourselves in embryo should lead a similar aquatic life to many of these animals!"—*Anderson on the Nervous System*.

sations with their associated muscular movements which make up the night, the turns and changes of position, unattended by any after-consciousness, and which are usually attributed to unremembered volitions, have, I believe, if the truth could be strictly ascertained, never been perceived.

To recur again to the *fœtus in utero*: as the mother is sensible of its movements after the fourth month, it is obvious its limbs are obedient to sensations before the brain is at all properly developed, and therefore before mind begins. The flexion and extension of the limbs, the kicking and elbowing which every mother knows are performed with considerable energy before birth, cannot be fairly attributed to volitions, unless the existence of perceptions and thoughts are at least presumable. Even after the child is born, it can only will those motions which are already obedient to sensations, as flexion, extension of the limbs, &c. It cannot originate a motion not connected with or trained to act with a sensation; it cannot, in short, accomplish a very unnatural or unusual movement. The first actions of the newborn infant are thus purely sentient, and have no more connexion with volition than those other actions which are the acknowledged results of instincts or sensations, as sucking, sneezing, coughing, respiring, &c. As it gets perceptions and ideas, its actions become gradually associated with volitions; but those volitions are still for a time confined to the instinctive or sentient movements; they then become connected with sensations, excited by seeing actions performed before us, and lead to imitative movements; last of all they become associated with perceptions of a more abstract nature, and follow patiently the thoughts of the mind.

It has been already observed, that purely sentient animals are not endowed with the higher of the special senses, whose exercise to any useful end requires the assistance of a percipient faculty. Common sensation which they enjoy, and which is generally diffused throughout their entire frames, seems capable of accomplishing all that is requisite to life, at least in that very lowest form of animal existence which betrays no mark by which it can be recognized, beyond a diffused sensibility. If a percipient faculty was not essential to the exercise of the higher

functions of vision and of hearing, there is no reason why these senses should have been confined to minute organs, or rather why they should not have been diffused throughout the frame like common sensation, so that sights and sounds and external feelings should be appreciated in common by the cutaneous nerves on all parts of the surface, as the odours of the rose, and musk, and valerian, are by the olfactory nerves.

There is no fact which more forcibly demonstrates the distinction between sensation and perception, than the vast distance observable between animals endowed merely with a diffused sensibility, and those possessed of such special senses as require the assistance of the lowest degree of the percipient faculty. Even multiplying the higher senses, or rendering them more acute, does not necessarily raise an animal in the scale of being, any more than multiplying or improving its instincts would. But rendering its perceptions permanent, and increasing its power of abstracting and comparing, add considerably to the perfection of its understanding. Some of the lower animals are said to possess a sixth and even a seventh sense, besides possessing those in a much greater degree of perfection which they enjoy in common with us; yet their vast inferiority would scarcely be lessened in the comparison were two of our special senses to be taken away.

It must readily occur to the reader, from all that has been stated, how much the confusion in which metaphysicians have involved themselves, about the nature of sensation and perception, must have tended to perplexity and error in their general estimate of affections of the mind. It seems strange, for instance, that what are called external affections of the mind—those sensations which relate to, and connect us with, the world about us—should be classed with internal affections; those perceptions, thoughts, and memories, of which our consciousness is made up, and which we feel might remain, though our external actions were altogether changed. What is there, we may ask, in sensation, in bodily enjoyment, or suffering, or pleasure, or pain? What is there even in our instincts or appetites, which all depend upon, or hold connexion with, the world we live in, and our relations to one another, which

induce us to identify them with conscious percipient and conscious mind—that mind which sees no essential or everlasting affinity between its thoughts and the things about it—which can conceive new conditions, and accommodate itself to new relations—and which acknowledges no necessity for its death, though the world were extinguished?

I am, after all, most ready to admit, that even in the present advanced state of physiological science, it is difficult to explain or discuss all the phenomena connected with sentient and percipient existence very minutely, without danger of committing some metaphysical absurdity. It may be, that every feeling includes some obscure intuitive sense of being; it may be, that perception, instead of being a distinct faculty, as Reid and others considered it, may be, as Brown conceived, "nothing more than a suggestion of memory or association, which differs in no respect from other suggestions, arising from other co-existences or successions of feelings equally uniform or frequent;" but, however these points may be eventually decided, it cannot affect the conclusions which have been followed out in these papers, so long as it is undeniable that evidences of sensation are displayed after ablation of the brain, but none of either perception or memory. The exposition of the greatest errors, or even of the most absurd reasoning, if such were detected, would yet go but a little way to shake the foundations upon which the opinions here advocated have been based, so long as it is unexplained how an animal possessing sensation, evincing spontaneity of movement, and evidently enjoying the pleasure of alacrity or action, of ease or of warmth, of hunger or satiety, admits of subdivision by the knife, each part still displaying the same phenomena which previously pertained to the whole? So long as it is unexplained how the brainless rabbit and the headless frog evince the ordinary movements of suffering when tortured, and make the ordinary efforts at escape; and, finally, so long as we remain unconvinced that, when cries are uttered by animals wanting the cerebral lobe, they experience no pain.

It has been said, it is true, that the experiments on living animals, from which these facts are deduced, are not to be trusted, and that the inferences from them are even contradicted by pa-

thological experience*. But no pathological experience or discovery can make it untrue, that movements to an end are made, and cries uttered, by the acephalous infant, or the brainless rabbit; or that signs of suffering are evinced, and efforts to free itself displayed by the headless frog. It has been said, on the other hand, by those who deny neither the facts nor the inferences deducible from them, and as if it offered a satisfactory explanation, "that, although in man the sensorium is exclusively confined to the brain, as we descend in the scale of being, it becomes more extended. That in some amphibia we may conjecture that the spinal cord partakes with the brain in all its faculties, and, as we advance to animals that have a still simpler organization, the brain entirely disappears, and the spinal cord appears to be substituted in its place."

A little consideration must convince any physiologist how very untenable are these assumptions, of a diffusion or transfer of a function or a faculty from one organ to another. No one was ever bold enough to imagine the functions of the liver or spleen could be transferred or extended to the kidneys, or to any other wholly dissimilar viscus; and, surely, in the shape and arrangement and anatomy of the brain, not to dwell on any other distinctions, there is as great dissimilarity to the spinal cord displayed as could exist between any of the viscera which differ most widely in function. When we cannot detect organs of vision or of hearing in any animal, we do not straightway suppose

* I have no doubt but when we acquire habits of observing the physiological symptoms arising from diseases of particular parts of the nervous system more accurately, we shall find our experience daily corroborate the results of experiments carefully performed on living animals. The rotatory motions, the retrograde and the motions forward which have been observed by Magendie in his experiments on the influence of the cerebellum on muscular motion, have been since noticed as direct results of diseases in animals; and I have myself seen, within the last month, an instance of disease within the ear, in which the symptoms strikingly resembled the effects occasioned by injuries of portions of that organ in the experiments of Fleurens. That celebrated physiologist found on dividing the semicircular canals of the ear in birds in certain directions a rotatory motion to the right or left, or motions of the head up or down was produced. In the instance of disease of the ear alluded to, in which a discharge from the organ had existed from childhood, the patient informed me, that whenever he pressed his thumb firmly on the mastoid process, he immediately spun round, and unless he removed the finger fell to the ground.

that these senses are transferred to other parts, but rather that they are wholly wanting. When the brain has been removed, or in cases where it never existed, why therefore should we not at once determine that the functions of that organ, whatever they might be, are wanting also? Or why should we rather venture a conjecture that in any, even the lowest form of vertebrated animals, the spinal cord becomes a substitute for the brain? "The investigations of comparative anatomy," says Mr. Grainger, "and the laborious inquiries into the process of development, have led to the establishment of one grand principle in the science of organization--the unity of structure. There is no truth in any branch of human knowledge fixed on a more firm basis than this; that although nature displays immense fertility in varying and modifying the form, and other physical characters, of the several organs, yet that there is in no one instance a departure from the first original type. This, the great law of the organic world, has been demonstrated in the osseous, nervous, glandular, and other systems, with amazing exactness; and, as a consequence, it has also been discovered that the human body, from the period of its first appearance as a semi-fluid and shapeless mass, till it attains its perfect formation, passes through many stages, in which its several organs temporarily assume the permanent structure of the lower animals. There is thus a chain of evidence, in which no link is wanting to prove what are, and what are not, analogous parts. Notwithstanding the complete establishment of this most important principle of the science of organization, it is still maintained that properties, that is to say, sensation (perception) and volition--which are known to be the special attributes of certain parts of the human brain, and which parts, although developed in an inferior degree, have still a real existence in the lower animals--become translated in these instances to another independent organ, possessing its own peculiar endowments--the spinal cord. If such a mode of inducing facts be recognized in physiology; if, in fact, the function of one organ may thus be transferred to another and distinct structure, merely to reconcile the anomalies of a crude and ill-supported hypothesis, all the great truths of modern anatomy have been discovered in vain."

[Concluded.]

of hearing,
OBSERVATIONS on the senses
ON the

COMPLICATED SURGICAL INJURIES,

INCLUDING GUN-SHOT AND OTHER WOUNDS.

By RUTHERFORD ALCOCK, K.T.S. &c.

Late Deputy Inspector-General of Hospitals with the Auxiliary Forces of Portugal and Spain.

(As delivered in his Lectures at Sydenham College School of Medicine.)

[Continued from p. 144.]

II.—On the various Characters of Gun-shot Wounds generally, and their Indications for Treatment. Also on some Complications by Fracture.

THE possibility of producing adhesion rapidly in gun-shot wounds should be well understood; for in some instances success is of the greatest importance. A case occurred in one of the Portuguese campaigns illustrating in a striking manner, that where the union of parts detached by a musket-shot is essential, such a result ought never to be despaired of, but every measure taken to procure union, as though it were an incised wound.

Lieutenant G—, in a sortie from Oporto, on the 24th of January, 1833, was struck by a musket-ball through the upper lip, tearing it down, and reversing it on the lower. At nearly the same moment, while turning round, a second ball struck him in the neck, and passed through his cheek on the opposite side, carrying away four of his molar teeth. Mr. Myers, the surgeon of his battalion—now practising in this town, and a gentleman of excellent judgment—saw him on the field, and very properly replaced the lip in accurate apposition, and confined the parts by means of two sutures through the substance of the lip. During the night the face and neck swelled enormously, attended with great pain, for which, within twelve hours, he was copiously bled. It was not until the next morning, when collecting the wounded British who might still be at St. João da Foz, that I saw him. A high state of inflammatory and febrile action had already fully set in. I had him removed into Oporto: and from the direction of the wound in the neck, immediately in front of the carotids, I insisted on his being placed in a wing of the English hospital arranged for the reception of officers, that he might be

constantly under my own eye and immediate care.

A strict antiphlogistic treatment was rigorously enforced: he was frequently bled, kept in a perfect state of repose, and only allowed to swallow a little cold tea or arrow-root in small quantities. The first efforts at deglutition nearly produced suffocation; but, with care, he managed better afterwards, although the effort was attended with pain and difficulty. Probably some branches of the vagus nerve distributed to the pharynx and larynx, and which are motor as well as sensitive, were injured by the course of the ball.

On the fourth or fifth day I cut away the sutures, which threatened to tear themselves out: the lip remained in perfect apposition, without any suppuration on a great extent of the wound, which stretched completely across the upper lip beyond the commissures of the mouth. About the seventh day a healthy suppuration was established in the neck, and also at the points of entrance and exit of the ball in the lip. The central part was united by a ragged line, marking the laceration the parts had suffered.

He recovered without a single unfavourable symptom: the tumefaction of the lip, which was very great at first, gradually subsided, until the wound was only marked by an irregular but tolerably smooth line, a little redder than the surrounding skin. The wounds in the neck and face healed, and some months after a portion of the alveolar processes exfoliated where the teeth had been driven out.

With respect to the first treatment of gun-shot wounds, it cannot be too simple. The pernicious effect of the indiscriminate use of bandages, sutures, and adhesive plasters, on the field, has been by no one more strongly enforced than by Mr. Guthrie, whose name stands so deservedly high in the annals of military surgery. During my service in Portugal and Spain I have had good opportunities of seeing the comparative advantages and disadvantages of each. For while my general order was fully complied with on the part of the English medical officers, "to use the simplest form of dressing, and particularly not to bind parts which in the natural course of things must naturally swell and enlarge with inflammation," I was in the habit of seeing a contrary rule

adopted by my Portuguese and Spanish colleagues. Sometimes I found even some of our own men, who had chanced to pass through their hands, with their limbs and bodies tightly swathed. Not seldom, as their ambulances were often considerably more to the rear than our own, they dressed our men a second time, who were passing to the hospitals from the field. Our friends not appearing to consider a man dressed without a bandage encircled his limb, a simple pledget of lint dipped in spirit or water, and a couple of strips of plaster to keep it in its place, like the fish and soup of a gourmand's dinner, seemed "to go for nothing," or merely to serve as a whet to the succeeding courses.

Many instances, some ludicrous and others lamentable, of this mischievous practice have come under my observation; to some of which I may refer hereafter. In the meantime let me mention another practice, which, but for my last campaign, I should not have thought worth mentioning, believing that it was exploded throughout Europe, wherever surgery was cultivated as a science.

I allude to the practice of converting a gun-shot wound into a pretty star, by means of a bistoury, dilating it in every direction.

During the assault of Irun, in 1837, a portion of the wounded of the besieging army were carried over the frontier into Behobia, to which place the French authorities had despatched an ambulance, surgeons, &c. On passing through the various quarters assigned to the wounded, to ascertain how many of the British, more particularly under my charge, were there, I saw, to my astonishment and dismay, sundry gentlemen of the French ambulance flourishing bistouries in every direction, dexterously and remorselessly, without hesitation or discrimination, adding to every gun-shot injury a dozen incised wounds. I could not help—although their patients were Spaniards, and consequently not so exclusively appertaining to me—to remonstrate; but the star-like process was not to be stopped, and I only congratulated myself on having previously despatched to the English wounded medical officers, of the Legion, by which they had all escaped.

In truth, from what I saw there, I am convinced military surgery among those gentlemen (I hope not in the

French army generally) must have sadly retrograded since Larrey taught and practised. At our simple dressings they shrugged their shoulders with an air of pity for our ignorance that was truly amusing, and I rejoiced exceedingly when the arrangements were completed for removing all our wounded back into Spain, which I did with all possible celerity.

These are some of the general and more superficial features of gun-shot wounds. Many observations of a similar tendency suggest themselves, but they must necessarily be brief and much curtailed, or I shall lose the opportunity of drawing your attention to still more important subjects.

In my last lecture, you will remember I pointed out the uncertainty attached to the patient's impression of the nature of his wound or the track of the ball; and a more extraordinary instance than any I adduced occurs to me now—additionally striking, inasmuch as the wounded man was a surgeon, although not serving in that capacity. He was struck by a musket-shot in the chest; and while examining his wound the first time, and subsequently on the succeeding day, his eager and anxious exclamation upon each occasion, was, "It is not a penetrating wound—I am sure it is not, sir!"

This non-penetrating wound had not only entered the chest, but the ball had carried away a portion of the apex of the heart! Of this case I shall speak more at length hereafter.

Equally uncertain are the indications to be drawn from the shock on the system, similar wounds producing various degrees in different individuals; a slight wound and a severe one sometimes giving you, in two men lying side by side, a nearly similar effect. Doubtless much of this depends upon peculiar idiosyncrasy, state of health, of the mind at the time, &c. It results, however, that you must neither implicitly rely upon the constitutional effects, nor be guided in the diagnosis, or even in treatment altogether, by such variable and uncertain signs. I have had two wounded men brought to me at the same moment; one shot through the thigh, and another with his shoulder torn off by a round shot; and the latter present less constitutional evidence of a violent shock than the former with a comparatively trifling wound.

This is not common, still it occurs sufficiently frequently to make it necessary you should be on your guard. However, it behoves a surgeon carefully to note the general effect, constitutional and local. This will often direct attention to the particular nature of the injury, and give information of effects where neither the eye, the probe, nor the finger, could reach. It enables the surgeon to make any local examination with more point and effect.

A man struck by a round shot, or receiving from a musket-ball a very severe or fatal injury, generally presents an appearance strongly indicative of its nature: a pale countenance, haggard eye, feeble or fluttering pulse, great prostration of strength, and a general faltering of the powers of life; the face often bedewed with a cold clammy perspiration. If stimulus, and a few words of confidence and hope—no mean stimulus—be not promptly administered, a man in this state is very likely to sink without an effort or any attempt at reaction in the system.

The injuries, on the other hand, which a man will suffer, and yet retain a calm demeanour and the perfect possession of his senses, is truly astonishing. At the assault of Irun, an officer was struck by a round shot, which tore his limb off at the upper third of his thigh, near to the hip. A medical officer on the spot promptly put a ligature on the femoral artery, before he allowed him to go a short distance to the rear. I met him on the road, and as I stopped the stretcher to know who was in it, he recognized me, and said, with perfect calmness, "Mr. A'Beckett, sir, has tied the artery." His pulse was feeble; his countenance blanched, though no bleeding had taken place. He was given a little brandy, and lived until the next day, but never rallied so as to render any operation justifiable.

On another occasion, an officer of rank, with considerable anxiety and disturbance in his countenance, was passing to the rear. Imagining he might be seriously injured, and no ambulance was so far in advance, I dismounted to see. On examining, I found a musket shot had passed across his buttocks, scarcely grazing—making, in fact, a black *wale*. The truth is, not having been able to see that part of his person, his imagination seemed to have figured a fearful wound; and when I told

him he was *quite pour la peur*, his countenance changed very oddly—still a little *decomposé*, as the French would describe it; half doubting its truth, and half wishing it might be untrue. He has since then been a viceroy and commander-in-chief. Nor would I by the anecdote impugn his courage. His only failing in this case he shares with all people who cannot see the back part of their person as well as the front.

The hæmorrhage which occurs in gun-shot wounds, in the first instance, is sometimes smart, without any large blood-vessel being wounded: if any branch can be readily discovered, it should be tied. But in the majority of cases it seldom lasts beyond a very few minutes, and stops either spontaneously or with the aid of a little cold water. Limbs torn off very rarely bleed. I have seen a great many, and never remember hæmorrhage from the main artery. Does this apply only to extremities?

After the action near Santarem, in 1834, to which allusion has already been made, I dressed one of the most ghastly wounds I ever witnessed. A Portuguese caçador sat on the ground, his tongue hanging out, a frightful spectacle! A grape-shot had struck him in the face, carrying away both lips, the superior maxillary bone, and most of the flesh covering, severely lacerating the tongue, smashing and crumbling away great part of the lower jaw. The man had perfect possession of his senses. There was very little

hæmorrhagic tendency, and, indeed, he seemed comparatively to suffer little pain.

Hæmorrhage more generally occurs about the twelfth day, when the sloughs detaching leave the mouths of any lacerated vessels open; and the parts in the neighbourhood, changed by disease, render such cases highly dangerous and exceedingly troublesome and difficult to manage. Some of the most complicated cases which have fallen under my care have been these, and productive of more anxiety than most others.

I think the number of these is greater than Mr. Guthrie has fixed as the average. He says, three or four in 1000. I do not think I ever had a batch of 300 wounded, without two, three, or more of such cases, though all may not require ligature: generally, however, they do require such an operation, and then almost invariably under very disadvantageous and trying circumstances. But on this part of the subject I shall have some further remarks to make presently.

In Portugal, I remember, in a set of 300, five cases occurred. In Spain, in one set of 400, five cases occurred: three in gun-shot fracture of femur; one in gun-shot wound of face; and one in gun-shot fracture of humerus.

In another set of 500, four cases: two from gun-shot fractures of bones of face, one of fibula, and one of radius into the elbow-joint. In 1350 cases under my charge at San Sebastian, nine; and in 197 officers, two cases—both gun-shot fractures of leg.

1350, rank and file, 9 cases of secondary hæmorrhage.

197, officers - - 2 ditto,

1547 11

Mean average about 7 per 1000.

The extremities are often the seat of very complicated injury. Comminuted fractures, lesion of vessels and nerves, and penetrating wounds into joints of every kind and form, requiring the most careful exercise of judgment to decide how far it be possible to save the limb; and therefore whether the attempt be justifiable. In the treatment demanding constant attention, and no ordinary exercise of knowledge, both medical and surgical; if such a division may be justly made in speaking of military surgeons, where no such arbitrary and purely conventional distinction can exist. I would rather say,

that in these injuries, the local adaptation of the means of cure, and the constitutional treatment, require to be most carefully adapted to the varying states of the patient and the nature of the injury, or no good result can be anticipated.

The most common of these complications is fracture; and a gun-shot fracture differs very much, both in its first characters and subsequent results, from the compound fractures generally met with in civil life by falls, cart-wheels, &c.

When a musket ball strikes a bone it generally splinters or shivers it into

many pieces, like brittle china. Here, you see, are several very perfect examples; this particularly—see fig. 1.

FIG. 1.

The bone, however, is not only thus broken into many pieces, but is very generally fissured upwards and downwards for several inches, as in these which I now show you; the consequence of this is, that when the fracture takes place in the lower or upper third of the bone, it is rare that these fissures do not extend into the joint, as you may observe has been the case in many of these preparations.

These fissures, extending into joints, are worthy of considerable attention as regards their capability of exciting destructive inflammation in the machinery of the articulation; in the various structures—osseous, cartilaginous, and serous or synovial—which enter into the formation of joints. There is no doubt that such mischief may ensue from a fissured bone. Nevertheless, it does not invariably follow, as you will see by this preparation, which offers one of the most beautiful specimens of the results of the inflammation in bone produced by injury, causing the most extensive caries, and of a widely fissured bone into the ankle joint, without any

destruction of such susceptible surfaces. Figs. 2, 3.

FIG. 2.—Posterior view.

- a, a, a, a.* Ends of fractured bone partially detached.
- b, b, b, b.* Callus.
- c, c.* Worm-eaten or partially absorbed fragments lying in the cavity of the tibia.
- d, d.* Cavity formed by a loss of substance, extending three inches in length and the whole diameter of the tibia.
- e, c.* Fracture extending through the articulation.

FIG. 3.

The following is a short abstract of the case:—Cornelius Curry, æt. 40, received in action on the 5th of May, 1836, a musket-shot; the ball entered about three inches above the malleolus internus, and passed out on the opposite side, fracturing and comminuting the bones in its passage. Three fragments of bone were removed on the field, and during the subsequent treatment 26 pieces were extracted.

Six days after the action I found the swelling of the limb not excessive, and constitutional disturbance slight. Towards the end of the first month the discharge became very profuse, and an abscess formed in the anterior aspect of the leg, which was opened, and a day or two later some lividity of the toes, with coldness of the foot, and griping pains in the abdomen, were observed. These disappeared in forty-eight hours, and on the 1st of June the wound was enlarged, and two large splinters of the tibia removed.

Frequent diarrhœa, griping, and more or less pain, with the formation of abscesses, marked the case during the second month, at the end of which, after carefully examining the limb, I made the following remarks:—

“There seems to be no very abundant formation of callus, and there is still great loss of substance where the fragments were removed. Small abscesses are continually forming in the neighbourhood, and there is much disease in the adjoining soft parts; ankle and foot considerably swelled; the leg presents a dilated granulating wound with a cavity in the centre, at the bottom of which the bone is seen denuded; health has suffered a little; bowels are rather lax, and he is subject to a feeling of sickness. Pulse is feeble; tongue pale, but clean; appetite, he says, is fair.”

At the end of the third month I again made careful notes of the state of the case.

“The limb is far from being in a satisfactory state: after twenty-two pieces of bone have been removed, it is still evident that further exfoliation is going on. The surrounding soft parts, for a considerable distance above and below, are in a very diseased state, and in all probability no effective union has taken place. Discharge healthy, but copious, six or eight ounces daily; pulsation of artery distinguishable from the motion of the pus; health, however, has suffered

less than might have been anticipated; bowels act regularly without medicine; tongue pale, but clean and moist; appetite tolerable; pulse feeble, 92. Full diet without meat; two ounces of sherry and an egg.

After this he rapidly declined. Erysipelas supervened; rapidly involved the cellular tissue of the whole limb; and on the 13th of August, the fourth month, he died. The following state of parts was found, on examination after death:—

The integuments of leg and thigh, on the inside up to the scrotum, livid; cellular tissue of the whole lower extremity, excepting outer side of thigh, infiltrated with serum; sloughing and disorganization of the tendons, muscles, and cellular tissue, observed in the vicinity of the fracture; part of this seemed caused by the pressure of a splinter of bone, about an inch in length, protruding from behind against the tendon of the extensor communis.

The fracture of the tibia was comminuted, and a very distinct fissure extended downwards and across the articulating surface of tibia its whole breadth. On examining the ankle-joint the synovial membrane was observed thickened; and that portion of it which covered the articulating surface of the tibia was of a blood-red colour, and separated from its cartilaginous attachment; a slight appearance of erosion of the cartilage was observed at the lower part of the articulating surface of the internal malleolus.”

There was an unusual and morbid quantity of fluid in the serous cavities. The whole cellular tissue was in some degree anasarcaous.

The notes of the *post-mortem* are very full, and minutely describe many other appearances of the diseased limb, bone, &c. But enough has been given for the present purpose. It is very evident, from the slight and almost doubtful erosion, in the middle of the fourth month, that no violent inflammation, but only a mild and chronic form, had been set up in the joint, for a considerable period; such, indeed, as might have been anticipated without any fissure or direct injury of the joint, from the extensive disease every where surrounding it.

Thus proving, that not only may a joint escape from a mere fissure, but from a widened and extensive crack

across the whole surface. It has been to establish this important fact that I have given at some length the details of the above example. There is no case in surgery probably which demands a nicer exercise of judgment, or more careful and maturely-weighed decision, than these gun-shot injuries of bone implicating joints. For if it be of the last importance that a surgeon should not wastefully peril the life of his patient by keeping on a limb hopelessly injured, it is scarcely less so, that he should not decide on removing a limb which, by time and care, may be saved and eventually cured.

Here, for instance, is a preparation of a femur, with partial fracture and fissures into the knee-joint (see fig. 4). I

FIG. 4.

The original dark line in the superior portion of the fracture marked the sketch made from it immediately after amputation. It was probably, however, not very closely copied.

never look at this without a feeling of doubt as to the propriety of, and almost regret at, the decision which caused the removal of the limb. It was my own decision, gentlemen; and although I still think the result of a trial to save the leg, under the circumstances, very doubtful, yet, perhaps, had I known as exactly as I do now the state of injury to the bone, I might possibly have reversed my decision, and endeavoured to save it. I did not hastily decide, however, or without carefully weighing

all the circumstances, which were shortly these:—

The patient, æt. 24, a private in the Legion, was admitted June 23, 1836, at ten o'clock at night, from the lines, with a wound above the knee, received (according to his account) from a swivel gun, at about two hundred paces distant. On examining the wound, the finger passed immediately upon a comminuted though evidently partial fracture of the femur, immediately above the internal condyle, the course of the wound being filled with nearly pulverized bone. The capsular ligament seemed to be opened, the finger glancing over the edge of a surface like that of the condyle where it enters into the articulation. The destruction of bone seemed considerable, and the laceration of soft parts, extending upwards and downwards for several inches, was greater, both as to extent and degree of injury, than any thing I have ever observed, except in wounds from cannon-shot.

The missile had passed evidently close to the under surface of the bone; hence I deemed it probable, that even if the artery was not torn across, its coats were bruised, and sloughing endangered.

Taking into consideration the destruction and injury of bone and soft parts—the danger to the artery, and probability that the joint was opened into, together with the certainty, from its close proximity, of serious mischief ensuing in it,—all these considerations, carefully weighed, led me to consider it a desperate case, notwithstanding the one favourable circumstance of the bone being only partially fractured. His consent could not be obtained till the succeeding morning, when inflammation was already making the limb assume a threatening aspect.

The limb was removed at my request, by Staff-Surgeon Dorset—a gentleman who had served with me not only in Spain, but all through the campaigns of Portugal, with great honour and credit. The first incision was made an inch and a half above the highest point of laceration. The vessels were preternaturally filled with blood. Four arteries were secured, and the vein bled so profusely when not confined, that I thought it desirable a ligature should be placed upon it.

On examination, the bone was found

less extensively broken than I had received the impression it was, although a considerable portion, as you see, above the condyle, was comminuted and carried away. The capsular ligament at one point was slightly torn, and diseased action had already commenced in the joint. The ball had, as I anticipated, passed between the artery and the bone, bruising it in its course, producing ecchymosis to some extent in the coat, though whether to such a degree as to bring on sloughing, may be doubtful.

The patient did very well, and fully recovered.

These, then, are the kinds of injuries, let me repeat, in which you will occasionally have very anxiously to weigh all the circumstances, and perhaps feel some difficulty in coming to a clear and satisfactory conclusion. They are always cases calling for knowledge and experience, and the sound judgment which can only be their result.

Two other cases of similar character and difficulty occurred, which will furnish good examples of how much may be adventured in some instances.

In the action fought by General Cordova, on the heights of Arlaban, in 1836, the Legion formed his right wing; and though only partially engaged, several men were wounded, among the rest one in the knee.

The surgeon of his regiment, who, with his wounded, was quartered in the same village as myself, on the evening of the action came to request my opinion as to the propriety of immediately amputating a man's leg. I had fortunately seen the man on the field a few moments after he fell, and, in accordance with the principle I have laid down never to lose the first opportunity, I forthwith dismounted, and carefully examined his wound.

A musket-ball had entered at the popliteal space, at the posterior surface of the external condyle, and passed through the bone at this point; my finger followed its track, ascertained that the condyle, though traversed, was not detached, and the ball, from its slanting direction, had probably not even opened the capsular ligament. I equally satisfied myself that the popliteal artery was safe.

I have no hesitation in saying that this first examination saved the man's leg, if not his life; for when I pro-

ceeded with the surgeon, I found it impossible, from the pain it inflicted, to make any minute investigation, and the limb putting on such an appearance with the exit and entrance of the ball across the joint, that it would most likely have been condemned. Finding, however, it was the same case, and having satisfied myself of the true nature and extent of the wound on the field, I thought it a case wherein the limb might be saved, and so decided. I had the satisfaction of seeing the man gradually recover, with a somewhat stiffened but straight and perfectly serviceable leg.

The second case occurred in an officer, Captain de B., at the assault of Irun, from whence he had been carried to Behobia. Amputation was decided to be the only resource; but the operation was deferred until I saw him.

A musket-ball had entered at the upper and outside of patella, and passing obliquely downwards, traversed the joint, making its exit low down in the popliteal space.

Carefully following its track with my finger, between the patella and the femur and tibia, I could ascertain neither fissure nor fracture, and finally came to the conclusion that the ball, opening the capsular ligament, had coursed obliquely across the articulation, between the surfaces of the bones, without materially injuring their structure. Under these circumstances I conceived the hope of saving the limb, and gave my opinion to that effect.

By free depletion, local and general—by a strict antiphlogistic treatment and great care—the inflammatory action was subdued. With the unremitting attention and judgment of Staff-surgeon Gannon, to whom, indeed, the chief merit is due, not only was the limb saved, but so good and useful a leg is the result, that on meeting the gentleman some time back, I observed with both pride and pleasure that he walked perfectly well and strongly on the injured side. So much so, that the British Army Medical Board did not conceive the permanent results warranted them recommending him for a pension.

Note.—In the three sketches, fig. 1 shews the bone as it appeared immediately after amputation; figs. 2 and 3, after maceration, when the splintering could be distinctly traced. In the superior portion the two cracks are per-

fectly closed, presenting a mere line, but taking an unusually oblique direction. At *a*, the crack extends within the insertion of the capsular ligament; and at *b*, about three lines beyond the edge of the articulating surface. At *c*, also, a close fissure extends round exactly to the articulating surface, sweeping round the external side of the femur in a very curved and oblique direction. In fig. 2, two other fissures are shewn, all perfectly closed but distinct; *d* is one, running upwards more than two inches; and *e*, which also extends into the articulating surface a couple of inches. Where the ball struck, the deeply broken cancellated structure of the bone is alone to be observed. There are eight fissures, three within the capsular ligament, and two of these passing from three to four lines across the articulating surface.

VARIOLOUS OPHTHALMIA.

BY J. F. MARSON,

Surgeon of the Small-Pox and Vaccination Hospital, London.

(Read at the Westminster Medical Society,
April 27, 1839.)

THERE is a popular belief that the eye is injured or lost in small-pox from one or more of the pustules of this disease forming on the cornea. The same opinion is generally entertained too by members of the profession, otherwise well-informed, and by our best writers; but so far as I have been able to observe the opinion is not correctly founded.

My position, as surgeon of the Small-Pox Hospital, affords me an opportunity of seeing this injury frequently, and I have noticed it with attention for the last three years, but in no one instance of those under my care has it arisen from the cause to which it is usually ascribed, nor have I ever seen a small-pox pustule formed on the eye. The eye itself appears to me to possess complete immunity from the eruption small-pox. It remains uninjured all through the eruptive stage of this disease. Although the pustules are invariably more numerous on the face than on any other part of the body, and extend to the inner margins of the eyelids, they never form on the conjunctival membrane—so far as I have seen—either where it

covers the globe of the eye or lines the palpebræ. Common inflammation in a few instances attacks the conjunctiva during the first 5 or 6 days; this I do not deny, but then it must be in a great measure independent of the eruption, as it occurs but very seldom, and is not the inflammation that leads ultimately to the destruction of the organ. Inflammation has been supposed by some to be caused by the diseased secretion of the Meibomian glands being confined within the closed eyelids, which is further stated by them to cause ulceration. This vitiated secretion might perhaps give rise to slight inflammation, but it does not produce destructive ulceration; that process is the effect of the state of body consequent on a severe attack of small-pox, followed by violent secondary fever. The two conditions are quite distinct. There will be in this inflammation arising in the early stage of the disease great redness, with what is called chemosis, continuing for a few days, but it subsides without future mischief to the part affected. The common abscess of small-pox, familiar to all practical men, forms on the eye between the conjunctival membrane and sclerotic coat, and also between the layers of the cornea, of which I may have seen five or six cases in the treatment of 1500, but this could not well be mistaken for one of the characteristic pustules of the disease. These abscesses were small, took place contemporaneously with abscesses in other parts of the body, and the eyes recovered unimpaired.

I may as well allude here to a deep-seated inflammation now and then occurring, of which I have seen three or four examples. It appears to destroy sight very speedily, without producing ulceration of the cornea, and is met with in persons who have small-pox in a very severe form, and who die on the seventh or eighth day. On looking carefully into the eyes of these patients the colour appears altered; there is a general cloudiness and vacant expression, and sight seems to be wholly gone in a very short time: the iris, retina, and all the interior and deep-seated parts of the eye I have no doubt are involved in this inflammation. Whether or not sight would be regained in case the body were restored to health, it is impossible to say, as I have never yet seen an instance of recovery.

But it is to the destructive ulceration

of the cornea, to that form of the disease which most frequently destroys the eye in small-pox, that I wish more particularly to request your attention. It is singular that our writers on ophthalmic surgery—men of great ability, experience, and observation—should have followed so exactly in the steps of each other, in giving what I consider an entirely wrong description of this affection. This error must be ascribed to the comparatively limited opportunities afforded to them of seeing the disease in its early stage. But I wonder that those writers have not taken the hint of its probable nature, from knowing that the eye is lost in precisely the same way, and under similar circumstances, from other exanthematous diseases—viz. measles and scarlatina (and in rare instances, also, from erysipelas and typhus). They would not, I suppose, contend that the papulæ of measles destroyed the eye; and yet, in small-pox, they attribute its loss entirely to the eruption. They state, that the conjunctival membrane is continuous with the skin, and separates under similar circumstances; and hence appear to conclude, and, I confess, with great apparent reason, that it must also be subject to the eruption of small-pox. Physiologically this may be correct, so far as it regards the skin; but it is mere theory so far as it relates to small-pox.

There is another strong argument against the ulcer in the eye being caused by one of the pustules of small-pox. They are beginning to subside on all other parts of the body, before the eye is attacked. It has been supposed, that as the cornea is so dense and unyielding, a longer time would be required to mature the pustule. The supposition is not good, for this reason: the great regularity observed in the appearance and disappearance of the spots on other parts of the body, beginning first on the face, and following in succession on the extremities, would hardly be departed from in the eye;—if a longer period were really required for their production in this part, it would still be doubtless a determinate one, and bear relation as to time in different patients; whereas the ulcer on the eye has its commencement, at all times, from the 10th to the 25th or 30th day succeeding the day of eruption. The most confluent cases of small-pox are daily seen, where the eruption is abundantly scattered over the face, without any af-

fection of the eyes at all; the proportion of those who suffer from variolous ophthalmia not being more than one in thirty-nine. This I know from having examined the register at the Small-pox Hospital, which is kept with great care, and in which every thing of importance regarding each patient is always noted. When I wish to arrive at something like a fact on any point, I take a thousand successive cases. I have done so in this instance, counting those who died as well as those who recovered, and find that twenty-six have suffered from variolous ophthalmia, which is one in thirty-nine; and of these, eleven lost an eye, about one in a hundred—precisely one and a tenth. Thus, then, I think we may fairly conclude, that if the conjunctiva were actually subject to the eruption of small-pox, as well as the skin, it would hardly escape mischief so often.

At the same time, it should be clearly understood that this destructive ulceration of the cornea is essentially allied to the inflammation of the skin produced by the exanthemata. The injury takes place when the system has been much reduced by inflammatory disease of the surface, and when fever still continues. The body may be quite as much debilitated by other diseases, also inflammatory, without the eye suffering. It is met with after small-pox, measles, scarlatina, erysipelas, and typhus. The latter, although not usually accompanied by eruption, has been associated with a good deal of petechiæ during the last two years, shewing the skin to be implicated in the derangement; and the liability of the cellular membrane to slough after typhus is well known. I have never yet seen any part of the conjunctiva slough but that covering the cornea; hence I suppose the seat of injury to be in the latter, or more frequently, perhaps—especially in mild cases—in the cellular membrane, between it and the conjunctiva.

The particular local affection that causes the destruction of the organ of vision in variola, begins generally on the eleventh or twelfth day, or later, from the first appearance of the eruption, and when the pustules on every other part of the body are subsiding. It comes on after the secondary fever has commenced, with redness and slight pain in the part affected, and very soon an ulcer is formed, having its seat almost invariably at the margin of the cornea: this continues to spread wi-

more or less rapidly, according to the degree of secondary fever present; in the more violent cases an ulcer being formed on each side of the cornea at the same time, shewing the disease to be advancing with great severity, and presenting a tolerably certain indication that the eye will be entirely lost. The ulceration passes through the different layers of the cornea, until the aqueous humour escapes, extending itself too laterally, and if the part of the cornea destroyed be large, the iris will protrude through the opening. In the worst cases there is usually hypopion, and when the matter is discharged the crystalline lens and vitreous humour escape; or the humours may escape from deep and extensive sloughing in the first instance, without the formation of matter; this being succeeded, of course, by the total annihilation of the form of the eye as well as the sight. In some instances the ulceration proceeds very rapidly. I have more than once seen the entire cornea swept away within forty-eight hours from the apparent commencement of the inflammation; and, what is singular, now and then the mischief goes on without the least pain to the patient, or his being aware that any thing is amiss with his eye. An example lately occurred, shewing the strong disposition for the ulcerative process to attack the margin of the cornea: it extended all round the anterior part of the eye to some depth, loosening three or four layers of the cornea almost in an entire state, as they may be separated from the dead eye by maceration.

This destructive ulceration, or sloughing, or whatever term may be given to it with most propriety, never takes place in a severe degree but when there is a high state of secondary fever present. That is a point which should be particularly remarked. The experienced practitioner, in the treatment of small-pox, will always know beforehand when it is likely to occur. There will be a hot and dry state of skin, rapid pulse, thirst, loaded tongue; these having been preceded by a very confluent state of the disease; and then it is that some fearful consequence may be apprehended, such as the loss of an eye, formation of large abscess, and sloughing of the cellular membrane, extending often over the greater portion of a limb—or, may be, formation or deposit of matter in one side of the chest. Some

of these serious results may be expected when the secondary fever runs high, experience alone directing the practised eye to an early knowledge of the probable termination.

The closer resemblance between sloughing of the eye and sloughing of the cellular membrane in other situations, and its occurring also about the same time, lead me to suppose that it is essentially of the same nature; and whoever has had much experience in the treatment of small-pox, and will give this subject attentive consideration, will, I think, come to the same conclusion. The cornea is composed of five or six layers, which must be allowed, as they are separable but not loose, to have some connecting medium; and it is reasonable to suppose that that connecting medium may bear resemblance to the cellular membrane elsewhere, and hence be subject to like attacks. It would be difficult, perhaps, to demonstrate this resemblance further than by analogy. Other soft parts, complete in themselves, but in close contiguity, have a connecting substance that we call cellular membrane. This substance, whatever it is, between the layers of the cornea, performs the same office. The beautiful structure of the eye would require it to be considerably modified, but still not altogether different, inasmuch as the object is the same, and nature being simple in her arrangements would vary it, we may presume, as little as possible. It may be asked, why does the eye suffer more frequently in small-pox, from sloughing, than any of the other soft parts? My answer would be, that I doubt whether it does. I have stated, that only one person in a hundred in the aggregate, is afflicted with the loss of an eye from small-pox; and if note were taken of the sloughing of the cellular membrane in other parts, it would be found to take place quite as often, if not oftener, in any individual part, as in the eye. Why one part should be fixed on in one person, and another in another, we are quite at a loss to explain; but of this I am sure, that during the last three years there is not any one external part of the body that I have not again and again seen the seat of sloughing of the cellular membrane.

The importance of the eye, and the disfigurement occasioned by its loss, might lead us to believe, perhaps, without careful inquiry, that it formed more frequently than any other the seat of

this injury. The scalp, palpebræ, about the beard in men, neck, elbow, knee, and dorsum of the foot, I feel quite certain are much oftener assailed than the eye by inflammation and sloughing. We also see in all those situations just enumerated, as well as in the eye, inflammation of a less degree of severity, which subsides without being followed by ulceration and sloughing of the skin and cellular membrane, still further illustrating the similarity of the two.

My object in bringing forward this subject has been to explain the pathology of the injury sustained by the eye in variola, more than to offer any remarks on its treatment: it may, however, be considered that that ought not to pass by altogether unnoticed.

Although it is to be lamented that in the severe forms of attack our efforts to save the eye will be of no avail, there are still others in which we can be of great use. Like all other diseases it has various grades. Patients are usually much reduced at the time the ulceration first makes its appearance, and all active treatment would be out of the question; but now and then it is seen in a stout full habit, with strong pulse, from whom it is desirable to take blood generally. This should be done with great care, but few being able to bear it. In others, if the eruption have subsided, so that the temple can be pretty well cleared, blood may be taken by cupping. This mode of abstracting blood will be found more eligible, in most instances, than general bleeding; or blood may be taken beneficially by leeches. After the fomentation, cold or tepid decoction of poppy should be applied to the eye, or a lotion of water with a small portion of spirit. I rather prefer simple water. Careful sponging of the eye two or three times a day with warm water, or warm milk and water, should always be enjoined: a purge given every second day, of calomel and rhubarb, if required, and saline medicine with antimony; milk diet. These means to be regulated according to circumstances.

Cases may be selected in which it is advisable to touch the ulcerated spot with lunar caustic scraped to a point; it appears sometimes to arrest the progress of the ulceration. I should rarely depend upon this alone; it forms one of several means worthy of consideration.

Two or three applications of leeches will often be found necessary; or cupping, followed on a subsequent day by leeches, regulated in number and repetition by the violence of the inflammation and strength of the patient. When the ulceration is accompanied by great debility, with but little remaining febrile excitement, depletion must not be thought of in any form. The patient should then be well nourished—perhaps wine may be necessary; our attention being mainly directed to the preservation of life on any terms.

I disapprove, in most instances, of the use of mercury given so as to affect the mouth; it only increases the ulcerative process. But we see sometimes the inflammation get into a chronic state, and the ulcer remain stationary, in which mercury may be used with much benefit. The inflammation disappears under its use as if by magic, and returns if the remedy be suddenly discontinued. I would have it given, however, in repeated doses, with great circumspection, as it is calculated to do harm when misapplied. Blisters to the temples should be tried, as they are often serviceable.

The prolapsed iris may render it desirable, in the chronic state, to resort to the application of belladonna to the brow; or the edge of the ulcer in the cornea may require to be touched with the nitrate of silver. It is almost impossible, in a paper of this sort, to allude to all the means of relief that may be necessary to suit each individual case; but I have mentioned those most likely to be advantageous; and finally, I have pleasure in stating, as the result of my experience, that although the appearance of the eye may be very unfavourable in cases where the inflammation and ulceration have been severe, but not so violent as to cause the discharge of the humour, in a few months after the patient has otherwise recovered his health, very great reparation usually takes place also in the eye. The leucomatous state will in a great measure disappear; and unless the ulcer have been deep, and exactly in the line of vision, very useful sight may be regained.

ON THE NEW VACCINE VIRUS.

To the Editor of the Medical Gazette.

SIR,

I HAVE pleasure in forwarding you a copy of the Report sent to me by the Glasgow Faculty of Medicine, which I am certain will be very interesting to many of the readers of the GAZETTE.

I am, sir,
Your obedient servant,
J. B. ESTLIN.

Bristol, April 23, 1839.

Report of the Committee appointed by the Glasgow Faculty of Medicine, to superintend the Employment of the New Virus in the Vaccine Institution.

Before proceeding to the immediate object of this Report, the Committee consider it their bounden duty to bear testimony to the prompt and courteous manner in which Mr. Estlin complied with the request of the Faculty of Medicine for a supply of the recent lymph, which he has been the honourable and praiseworthy means of introducing to the notice of the profession.

As the letter inclosing Mr. Estlin's vaccine points stated that the use of this virus was occasionally followed by intense inflammation, and even abscess, in the situation of the vaccine vesicle, your Committee, fearing lest the occurrence of such accidents might prove detrimental to the institution, and diminish their opportunities of observation, at first applied the virus to one case only, and then to a single puncture on one of the arms. On the eighth day this pock presented a most favourable appearance; and that your Committee might have a fair opportunity of judging of the course of the pock, it was left uninjured, and its progress observed from time to time by one of their number, who reported favourably of it throughout.

After this the virus was brought fairly into use; and since the 28th of December 43 children have been inoculated with it, and upwards of 150 charges have been distributed to members and other practitioners in town and country, so that this virus is now extensively diffused over this neighbourhood; and

as your Committee have been at the pains to ascertain the results of the experience of many of these practitioners among their own private patients, they have embodied these results with what fell under their own observation at the Institution.

The first point in connexion with the new virus which your Committee would bring under notice, is the superior success attending its employment. Among these 43 cases not a single instance is recorded in which it had failed; whereas, in the 43 cases immediately preceding these on the record, ten instances of failure, and nine of spurious or imperfect vesicles, are noted. To this subject your Committee will again recur.

2dly. As to the appearance of the vesicle on the eighth day, this has been in some degree modified by the size of the scratch, or scratches, made in vaccination; but at this period the vesicle has generally been in an immature rather than an advanced state, and the areola around it has been very slight, and in many cases entirely wanting. The centre of the vesicle has generally been much depressed, bearing the appearance of being firmly adherent to the substance beneath, and this appearance becomes still more marked as the pock becomes more matured. Indeed, the surface of the pock upon the eighth day has been rather flattened, and the quantity of virus contained has, in the majority of cases, been small; but this has always been perfectly pellucid, untinged by purulent admixture, and apparently in the most favourable state for the development of its peculiar properties.

3dly. The progress of the pock from the eighth day, or period of maturation, as this has been commonly considered, to the point of cicatrization, has generally occupied from ten to fourteen days; and although in none of the cases which have come under the observation of your committee has the inflammation attending the pock run higher than they have repeatedly seen it in former cases, yet in a few instances they have about the fourteenth day observed in the site of the pock a deep cavity, resembling not a little that formed by caustic when the eschar has nearly dropped off. This deep and angry-looking sore has alarmed the friends of the child very much; but

in none of the cases did the ulceration shew any disposition to extend. Under the application of some mild absorbing powder, the sore has gradually filled up, taken on a scab, and become cicatrized; and in a few cases, when it has been examined, the cicatrix has been well marked.

4thly. The constitutional symptoms have been, generally speaking, slight; but in some cases which have been closely under our observation they have come on early, been severe, and seemed to have no relation to the state of the local affection.

Before closing the report, your Committee feel called upon to make a few remarks upon the failures which occasionally occur in vaccination, and upon the probable causes to which this may be attributed, premising, that your Committee found these remarks chiefly upon the last volume of the Vaccine Record, which extends over a period of rather more than three years, viz. from August 1835 till December 1838, and embraces 2041 cases. During a portion of that time the appearance of each pock was minutely recorded, and during the whole period any deviation from the usual routine was noticed, and the state of the child's health, and especially the condition of the skin, accurately recorded.

From this record it appears, that at four different periods there occurred an entire degeneration of the lymph, and a consequent complete failure of the vaccination. The record farther shews that these failures have been preceded by certain circumstances which the Committee think worthy of being noted. In the first place, a few isolated repetitions are recorded. In the second place, the pocks are remarked as being highly inflamed, or surrounded by a very diffuse areola. In the third place, many premature pocks are recorded; and finally, a vast succession of failures led to the renewal of the supply of matter from a new quarter.

The last of these entire degenerations occurred immediately before the introduction of Mr. Estlin's virus; and the whole of the children vaccinated upon the day week preceding, presented, instead of true vesicles, raw surfaces, resembling very closely spots that had been vesicated and then denuded of the cuticle. Some of these surfaces were perfectly dry, and thinly scabbed over; others were pulpy look-

ing, and gave issue to a profuse discharge of serum. In fact, it appeared that in these cases the pock had run through its entire course in the time usually allotted to the mere development of the vesicle.

Your Committee, with these facts before them, are inclined to regard want of care in the selection of the pock to be vaccinated from, as one of the prime causes of the failures which have occurred, and even of that degeneration of the lymph which has been complained of; and they would earnestly recommend the selection of pocks for vaccination which are free from areola or much surrounding inflammation, as there is every reason to believe, that when a high degree of inflammation accompanies the vesicle on the eighth day, the pock is too mature to yield an active and pure virus.

Indeed, when the pocks, upon any given day, present the inflammatory character, your Committee would rather recommend the falling back upon the vaccine points than making use of matter from the arms of the children; and, that a good supply of these points may be always on hand, your Committee would farther recommend that a number of them should be charged from time to time, from any decidedly characteristic pock which may come under observation. At all events, your Committee think it would be proper to renew the supply at intervals of two or three months, using the matter laid past at these intervals in preference to the recent lymph. In this manner it will be obvious, that at the end of thirteen years, the matter will only be as many degrees removed from the original source as, in the common routine, it is in one. Your Committee would farther recommend that the appearance of each pock should be noted in the record.

In conclusion, with the conviction that the matter (in our institution, at least) has shewn a tendency to the production of premature vesicles, your Committee regard the introduction of Mr. Estlin's lymph as a great boon to the public and to the profession; as it is very questionable whether these premature vesicles confer that immunity from the variolous disease which vaccination is calculated to bestow.

(Signed) J. P. GLEN,
CONVENOR.

ANALYSIS OF BRONZE.

To the Editor of the Medical Gazette.

SIR,

THE kindness of Mr. Richard Battley (whose laboratory is always open for scientific purposes, and whose name is so well known to the profession in general, and to the readers of the *MEDICAL GAZETTE* in particular, that any eulogium from me would be unnecessary), has put it in my power to send the following details of an analysis of the "bronze," which may perhaps possess sufficient interest to render them worthy of a place in your journal.

The sample selected for the purpose was of the bronze sold at thirty-five shillings per pound; and I cannot do better than use the words of Mr. W. E. Heathfield, chemical assistant in Mr. Battley's laboratory, whose kindness and unwearying assiduity have enabled me thus to offer you the results of his investigations.

The appearance of the bronze is that of a highly burnished golden yellow powder, consisting, when examined closely, of minute spiculae, adhering to the paper in which the bronze is folded, and leaving a smooth and almost greasy feeling when rubbed between the fingers. The bronze being put into a glass, and water added, a portion rose to the surface and floated there, forming a beautiful film, like a coating of gold leaf. When heated in a platina crucible over a lamp, and brought to a temperature of about 310° , the bronze gave off some oily vapour, and suddenly became ignited throughout the mass, burning like tinder; and on discontinuing the heat, the brilliant yellow coloured powder had disappeared, a dull brown colour being left; but if the heat was withdrawn just before ignition took place, a dull brass colour was the result; and the shade of hue varying between that of copper and that of brass, seemed to depend upon the degree of heat applied.

On heating it in a glass retort without access of air, the colour changed more slowly, and ignition did not follow; but a few drops of oil trickled down the beak of the retort, and a little steam also was formed, probably from a decomposition of a portion of the oil.

When heated alone on charcoal, under the blowpipe, it immediately changed colour; the oil was dissipated; a minute quantity of white deposit coated the charcoal, and numerous metallic globules resembling copper were produced.

Strong hydrochloric acid acted only partially on the powder, not dissolving it entirely; no more did strong sulphuric acid, even when assisted by heat. Strong nitric acid acted upon it, producing violent effervescence, and an abundant disengagement of nitrous fumes; still it did not cause complete solution, a small quantity of greyish powder being left unacted upon. To the nitric solution, which was of a deep green hue, hydrochloric acid was added, and a white precipitate took place, wholly insoluble in nitric acid, but immediately disappearing on the addition of a few drops of liquid ammonia; and this precipitate, on exposure to light, assumed a slate colour, indicating the presence of silver.

Ferrocyanate of potash being added to a portion of the solution, produced a chocolate-coloured precipitate; and on the addition of liquid ammonia to another portion, a plentiful precipitate was obtained, wholly soluble in an excess of the precipitant, and producing the beautiful azure blue colour characteristic of copper.

The greyish powder left on the filter after the action of nitric acid resisted the action of acids most obstinately; nitro-hydrochloric acid, however, after long-continued boiling, took up a little of it; and the solution was turned to a brownish black by a stream of sulphuretted hydrogen. The acidulated solution being neutralized by a solution of pure caustic potash, a white precipitate appeared, which, being collected, dried, and ignited in a crucible, yielded the lemon yellow colour distinguishing the hydrated peroxide of tin.

A portion of the bronze was boiled in a strong solution of caustic potash for eighteen hours; and this process materially diminished its lustre, leaving it of a dull brass colour, but did not wholly deprive it of the oil, as was indicated by the appearance of an oily vapour on the heat of a lamp being applied. The bronze was next digested for thirty-six hours in liquid ammonia, at a heat of about 120° : the effect of the alkali was to deprive it of all brilliancy, leaving the

ammonia tinged deep blue, and converting the bronze into a dull brown coloured powder, which, under the microscope, appeared to contain many particles of metallic copper.

Two hundred grains of bronze being digested in dilute nitric acid at a gentle heat, rapid action took place, accompanied with much effervescence and disengagement of nitrous fumes, and leaving undissolved some greyish white powder, which, after a second boiling in acid, weighed twenty grains. The nitric solution was of a deep green colour; and to this hydrochloric acid was added, as long as any precipitate fell; and this precipitate being first washed with dilute nitric acid, and afterwards with distilled water, weighed, when dry, twelve grains, and contained nine

grains of metallic silver. A polished iron rod was next immersed in the solution, and speedily became coated with metallic copper, weighing, after due eduleoration, one hundred and sixty-six grains. The portion unacted upon by the nitric acid, and weighing twenty grains, was next boiled in nitro-hydrochloric acid; a little of it was dissolved, and a dark brown precipitate produced by the addition of liquid sulphuretted hydrogen; a rod of zinc placed in the solution became coated with tin; and the nitro-hydrochloric liquor being evaporated to dryness and water added, yielded a white precipitate, determining the existence of metallic tin in the quantity of sixteen grains.

| | | |
|---|--------|-------------|
| Thus, 200 grains of bronze contain— | Silver | 9 grains. |
| | Copper | 166 grains. |
| | Tin | 16 grains. |
| | | <hr/> |
| | | 191 |
| Oil, dissipated by heat and loss in the process | | 9 |
| | | <hr/> |
| | | 200 grains. |

The results obtained in the foregoing processes were confirmed by the following experiments:—

A hundred grains of bronze were treated with dilute nitric acid, at a gentle heat, and an incomplete solution was the result, five grains of greyish powder being left; the liquor passed the filter with difficulty, being prevented by the separation of the oil; and on evaporation of the nitrate and subsequent dilution, five grains more of this powder, insoluble in nitric acid, were obtained. Hydrochloric acid was next added to the nitric solution, and a precipitate fell weighing six grains, and indicating four grains and a half of metallic silver.

Caustic potash, in considerable excess, was next mixed with the nitric solution, and boiling heat applied for fifteen minutes; a blue precipitate was the result, becoming brown on exposure to heat, weighing, after eduleoration and ignition, a hundred and four grains, and indicating eighty-three grains of metallic copper. The remaining solution being perfectly neutralized with hydrochloric acid, and a stream of sulphuretted hydrogen transmitted through the liquor, no precipitation resulted, proving the absence of zinc. The undissolved residue which was treated with nitric

acid in the first instance, was found to be partially soluble in hydrochloric acid, the precipitate, however, which took place on the addition of water, was wholly so; and the solution presented, with sulphuretted hydrogen, &c. &c., all the characteristic appearances of tin, so the metallic tin may be estimated at eight grains.

Thus 100 parts of bronze contain—

| | | |
|-------------------|-------------|-------|
| | Silver | 4½ |
| | Copper | 83 |
| | Tin | 8 |
| | | <hr/> |
| | | 95½ |
| Oil and loss | | 4½ |
| | | <hr/> |
| | | 100 |

I had hoped to have been able to have offered other analyses of different bronzes, which might, perhaps, explain the reason why one sort should act so much more violently than another; as, for instance, the cheaper sort mentioned by A. B. An analysis of this was performed by Mr. Sandall, of the chemical laboratory of St. Thomas's Hospital, who kindly volunteered his aid, and the subjoined are the results which he obtained in his experiments, which, in justice to that gentleman, I must state

were interrupted and hurried by circumstances over which he had no control.

| | |
|---------------|-------|
| Copper..... | 17.64 |
| Tin | 2.35 |
| Silver | 1.23 |
| Zinc | 3.50 |
| Water and Oil | 0.82 |
| Loss | 1.73 |

27.26

It will be observed that, besides the different proportions of the other metals, zinc forms a component part of this bronze; but how far its presence could render the action of the bronze more violent, I confess myself wholly ignorant. Indeed the action of zinc, as a medicine, appears to be very little understood, and it has not been in my power to obtain any *renseignemens* as to whether the zinc miners or smelters are affected by the nature of their occupation or not, or, if they are, in what manner.

Nothing is more probable than that the bronze varies much in different samples, and that each manufacturer has his own process and proportions for mixing the metal used for the purpose; and it is also not unlikely that the violence of the effects of the cheaper sort may have been rather exaggerated by my informant.

With regard to the treatment of those suffering from the use of the bronze, I have said but little; for few cases have come under my immediate care, though many under my notice, and quite enough in number to establish the fact of its pernicious influence on the workmen employing it, and to prove that from its use—

“*Macies et nova febrim
Terris incubuit cohors.*”

Such, probably, will always prove the case to a certain extent: as our arts improve, new inconveniences must arise, and new diseases result; and in the course of time, from the march of science and perfection of processes, new remedies will be discovered, and the evil effects in their turn be removed.

The use of the respirator would probably be of great service to the bronze workers, by preventing the inhalation and swallowing of the finely subdivided metallic dust. This would, to a great extent, obviate those symptoms which I have ventured to call constitutional, and referred to the poison being taken di-

rectly into the lungs and stomach. A careful observance of cleanliness would also prevent the workmen from suffering so severely from the most distressing local symptoms caused by the direct application of the powder.

Let me, however, repeat my hope, that this very brief and incomplete notice of the effects of this powder, may arouse the attention of those of my medical brethren who, from their larger opportunities of observing disease in our great hospitals and manufacturing towns, will be able to favour the profession with the results of their experience as to the cause and treatment of this new complaint. If it should have the effect of calling their attention, and that of our manufacturing chemists, to this disease—its origin, its nature, the mode of obviating and the mode of curing it—it will be a source of the greatest satisfaction to me; and in this hope, allow me to sign myself, sir,

Your obedient servant,

GURNEY TURNER.

General Dispensary,
Aldersgate Street, April 23, 1839.

CICERO.

EXPERIMENTS ON LIVING ANIMALS.

In our last article on this subject, we endeavoured (and we hope successfully) to shew, that if the result of such experiments be only the acquisition of truth, they are at least as justifiable as the commonly sanctioned and encouraged pursuits of hunting, fishing, shooting, &c. (when not followed for the sake of subsistence), or as the studies of those branches of natural history in which pain and death are inflicted upon living and sensitive creatures. In all these, and in a thousand other cases of the same kind, pain is inflicted upon animals solely for the gratification of mankind; and the concurrent opi-

nion of a vast majority of the world sanctions, and thereby appears to justify them—at least in most instances. Vivisection is, perhaps, more generally discountenanced than the rest; but this is not because it presents, when properly practised, any peculiar characteristics of cruelty, but because it can be the pursuit of only a few, and because the majority of people can neither understand nor appreciate the intellectual pleasures of its object—the discovery and possession of truth—though they are all alive to the more animal delights of manly sports.

But we promised to prove that experiments on living animals are allowable on higher grounds than the commonly admitted principle, that the pursuit of pleasure to man is justifiable, under certain limitations, although it causes pain and death to his fellow-creatures; and we will now point out some of the many cases in which such experiments have led to eminently and vitally useful discoveries.

If every man in the present day, who received a wound of a large artery, was by it consigned to certain death, either immediately or after lingering illness and the tortures of attempted cures—if for every aneurism, amputation were deemed necessary, and in every amputation the application of a hot iron, or the use of red-hot knives, were the only known means for arresting the hæmorrhage that would ensue—there are few who know any thing of the frequency and the terror of such injuries, but would deem the discovery of alleviations for them cheaply bought at any price of pain or death to lower animals. Yet, for all these sources of human suffering and destruction, experimental science has furnished secure and comparatively painless remedies. It would now be impossible to calculate in how many thousand instances, besides those just enumerated, life has been prolonged,

and pain decreased, by a knowledge of the mere fact and method of the blood's circulation; yet this was, as Harvey tells us, only obtained "*cum multis vivorum dissectionibus* * ;"—"*multa frequenter et varia animalia, viva introspeciendo*"; by observations "*in cordibus omnium adhuc viventium animalium, aperto pectore, et dissecta capsula quæ cor immediate circumcludit.*" If man could by any other means have attained this knowledge of the circulation, Harvey would assuredly have acquired it, though its phenomena were so obscure that his immediate predecessors believed they were "known to God alone." And will any think the destruction of animal life, which he caused, to have been unjustifiable, when they have considered that for every animal sacrificed, at least one human life has been saved, and thousands of human pains have been alleviated?

Thus much for the general discovery of the circulation, the knowledge of which extends its benefits through every department of medical and surgical practice, and daily confers blessings on all the civilized world. But its applications in many cases could not be certainly acquired without the infliction of farther suffering upon animals. The use of the ligature of arteries was never surely practised till the changes to which it gave rise, and the certainty of its value had been ascertained by experiments; and this, for the want of which, lives innumerable were sacrificed only a few centuries ago, and in place of which a red-hot iron was applied to almost every wound that bled profusely; this is now repaying the lives of animals which it required, by an abundant harvest of life and comfort to mankind. Again, the most splendid achievement of modern surgery—the cure of aneu-

* It should be enough to sanction the occasional use of vivisection, that these words commence Harvey's Treatise—the most important to the life of man that ever was published.

risms, by tying the artery on which they are formed, was the work of Hunter, an occasional vivisector; and can he be fairly stigmatized, if to attain such an end, he did not hesitate to employ what are foolishly called cruel means? Ask those, whose lives and limbs he and his successors have saved.

These may suffice as examples. Almost as many might be given in nearly every other system of the human body, besides the circulatory which we have chosen, in which facts, discovered by experiments on living animals, and in many cases discoverable by no other means, have been the source of the greatest comforts to mankind. The knowledge of the mode of reparation of fractures and wounds generally;—of the origin and seat of many diseases of the nervous system;—of the powers of the body in the repair of injuries and diseases;—in short, of nearly all that is known and practised in medicine, has been in part acquired by this method of investigation.

If, then, vivisection has conferred these benefits, is it not fairly justified? It may not be absolutely necessary, for men might have died under many circumstances from which they are now saved, perhaps without much injury to their survivors. But it is at least as necessary as many death and pain-inflicting practices which even Dr. Styles does not repudiate, as the eating of game or poultry, of small fish, and of all delicacies and superfluities that once enjoyed life. What is there that we enjoy or need for food, or covering, that is not obtained by pain to our inferiors? That alone are we completely justified in using, if we are not justified in occasionally resorting to experiments on living animals. Experiments are essential to the progress of medicine; and men may choose whether they shall be made on themselves or on brutes.

To express, then, our concluding opinion: we think that, *under certain restrictions*, experiments made on living animals in pursuit of truth, for its own sake only, are as justifiable as any of the sports or sciences in which similar pain and death are inflicted, amongst which, mentioning only those which receive the sanction and encouragement of estimable men, we would include the sports (not the trades) of hunting, fishing, and shooting, in all their varieties; and the studies of all branches of zoology for which private collections are made. And we hold that the same experiments, if they lead to the good of mankind, by suggesting remedies for disease and pain, or providing the means of lengthening life, are not only justifiable but laudable, and worthy of encouragement by public sanction and approbation.

But let us now mention some of the restrictions which should be placed upon their performance, beyond those which the commonest sense of humanity and decency would teach. The first must of course be, that this mode of investigation should never be had recourse to till it is sufficiently clear that the fact pursued neither is, nor can be, proved by any other evidence which is within reach, nor by any other more gentle mode of inquiry. We would enter as strong a protest as any—the warmest professor of humanity, against the too common habit of employing this class of experiments as the shortest road to the learning of truths which are either already established, or might be settled by evidence which has been already published. The man who, either from indolence, or from a desire to appear original, neglects the study of previous records, is, in every experiment which he performs for the discovery of what they contain, guilty of wanton and inexcusable cruelty. It would be always

well to remember, too, that the slow and patient investigation of the facts naturally presented to us by disease or accident, is far better than the hasty immature manner in which experimental attempts to imitate them must always be examined. Too often animals are tortured, because the facts are thought to occur too slowly in the course of nature; and the conclusions too often correspond in their crudeness with the hastiness of the study.

But supposing that it appears that the anticipated fact is not and cannot yet be determined, far more precaution ought to be employed than is usual, to decide before experimenting what is at present the exact state of the question, and what are the points that are yet undecided, that they only may be looked for. It is far too common for experimenters to proceed at hazard, and some of them seem to cut up dogs as if merely to see what will come of them. Such practices as these cannot be too strongly censured; they are as contrary to philosophy as to humanity.

The practice of repeating experiments of which the results are already well known is even more odious. Yet these are what are most commonly exhibited to classes—to teach anatomy, it is said, but really to obtain *éclat* for the lecturer, who is deemed original and enterprising for it. There can be no need whatever for such a practice; no man will be wiser for having seen animals tortured; and if the lecturer's word be deserving of confidence, no pupil will refuse to receive his assurance of facts, or desire to have them illustrated by cruelty. The majority of M. Magendie's experiments are of this class; and we are quite sure that no man has added so little to the possessions of science, in proportion to the cost of its character, as he has done. He has drawn down odium on the whole profession of scientific medicine, and the

boons he has obtained for it are in no degree commensurate with this injury.

When the necessity of an experiment is thus fairly and conscientiously decided, every means should be resorted to, that its performance may be attended with the least possible pain, and that at the same time all the information required may be securely and certainly obtained. We cannot here point out all the precautions necessary for these purposes—we are sorry to say that only experience will teach some of them—but the majority will be suggested by humanity and common sense. In all possible cases the animal should be deprived of sensation, and artificial respiration maintained. Wherever it is admissible, animals already consigned for destruction, or the lower animals, should be employed; for the latter will suffer far less pain, and for the former it will be but a somewhat more painful mode of death. In every case the greatest expedition that is consistent with security should be observed. The pain should never be prolonged to gratify curiosity; and life should afterwards be saved if possible, and the necessary pain compensated by kindness and the administration of every comfort.

If these and some similar restrictions be carefully and kindly observed, a man may experiment on living matter with as good a conscience as he can on the dead. Let him only fairly consider by what motives he is induced to resort to such an investigation; that they are either to ascertain some well-indicated and unknown fact which cannot else be decided, or that they are to attain that which will be beneficial to his fellow-men, and in the present constitution of society he may fairly claim its approbation.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

April 23d, 1839.

SIR B. C. BRODIE IN THE CHAIR.

A Case of Congenital Absence of the Pericardium. By T. BLIZARD CURLING, Esq., Assistant-Surgeon to the London Hospital, &c.

THIS observation was made on the body of a gardener, aged 46, who, after exposure to wet, was admitted to the London Hospital in January 1839, affected with paralysis, commencing in the lower extremities, and died in about three weeks. After death, besides some other interesting and rare morbid appearances, on raising the sternum with the costal cartilages, the heart was seen lying close in the cavity of the left pleura, in immediate contact with the left lung, without any appearance whatever of pericardial sac. The heart, which was invested with the reflected portion of a pericardium, was rather large and flabby, and in its natural position. There was a small white opaque spot on the left ventricle, and also another on the left lung, where it was most exposed to the heart's motion. The author describes the relation of the left pleura to the great vessels and to the right pleura, and the deviation from its usual course of the left phrenic nerve, which he considers to be a discriminative mark of congenital deficiency of pericardium from that which may ensue from diseases. The only semblance of pericardial sac that could be discovered, was a pouch of serous membrane above the diaphragm, at the point where the lower vena cava joins the heart. The author compares this case with those which he considers genuine similar cases recorded by other writers, and concludes with some remarks on the beneficial effects of a pericardial sac in isolating the heart, and thereby protecting it from the communication of inflammatory affections so frequently occurring in the lung.

Remarks upon an Instrument for the Cure of Club-Foot; with Description of a Case of Congenital Varus, representing one of the highest Degrees of that Deformity, cured at the Age of 23 Years, by dividing the Tendo-Achillis, the Tendon of the Musculus Abductor Pollicis Pedis, and the Plantar Fascia. By Dr. GUSTAVUS KRAUSS. Communicated by W. LAWRENCE, Esq. F.R.S. &c.

The author's object in this paper is chiefly to impress upon the minds of sur-

geons operating for the relief of the different kinds of club-foot, that the success of the treatment, especially in aggravated cases, depends mainly on the perfection of the instrumental means employed for maintaining the position or form of the foot after the division of the tendons shall have been effected. With this view he gives at some length the details of a case of great deformity in a person of 23 years of age, in whom he operated in the several ways described in the title, in Dec. 1837, and subsequently. Casts were produced of the legs of this patient prior and subsequent to the several operations, and the instruments employed were also exhibited in illustration of the descriptions in the paper, the ingenious adaptation of which, to the various ends proposed it would be impossible adequately to comprehend without manual investigation.

PHYSICAL SOCIETY, GUY'S HOSPITAL.

April 20, 1839.

H. GREENWOOD, ESQ. IN THE CHAIR.

Treatment of Syphilitic Iritis.

MR. MENZIES read a case of syphilitic iritis.

Hannah Briggs, æt. 20, was admitted into Dorcas ward, during the autumn of last year, under Mr. Cooper, for a syphilitic scaly eruption following a primary sore and bubo. She is a woman of cachectic appearance, brought on by her habits of living and by the abuse of mercury, which she has taken in large quantities; she has mercurial pains in her joints and limbs. Mr. Cooper ordered her iodine and sarsaparilla, under which treatment she rapidly improved. On the night of Saturday, 1st December, she was roused from sleep by a violent shooting pain in the eyelids, which subsided towards morning; she felt the pains at intervals during next day, and also observed a more than ordinary lacrymal secretion; towards night the pain again returned, but was much relieved by the application of tepid fomentation.

Dec 3.—She complains of pain in the balls of both eyes, and in the temples; there is profuse lacrymation; the conjunctival vessels are slightly injected, not sufficiently, however, to obscure those of the sclerotic, which may be distinctly seen as a zone of a foxy or cinnamon-colour round the cornea. Irides dull and sluggish in their movements; pupils of natural size. Mr. Cooper ordered—

V.S. ad 3xiv.; Hydrarg. Chlorid. gr. iss.;

Pulv. Opii, gr. 4, *tertia* quaque horâ;
and blisters behind the ears.

4th.—Has had a restless night; pain in the eyes, forehead, and temples, severe; vision indistinct; the fibrous texture of the irides lost, from the effusion of lymph of a light-brown colour. She was cupped to twenty-four ounces, and ordered to continue.

5th.—Much worse; iris of left eye more contracted; pupils are irregular; irides covered with diffused patches of lymph, not taking on a circumscribed or raised appearance; cornea quite clear; sclerotic highly injected. It was discovered that the blisters had, by some mistake, not been applied, and the calomel and opium not given. Mr. Morgan was requested to see the patient: he ordered—

Cucurbit. cruent. Nuchæ, ad 3xx.;
Empl. Cantharid. postea; Hydrag.
Chloridi. gr. iij.; Pulv. Ipecac. gr. iij.
4tis horis.

6th.—Has not slept; pain in the head and ball of the eye intolerable; complains of flashes of light; cornea clear; irides widely dilated; vision nearly extinct.

Cucurbit. cruent. ad 3xx. et perstet.

7th.—There is no diminution of suffering; cannot distinguish the light; pupils widely dilated.

V. S. ad 3xv. Pergat.

This was followed by a relief of her symptoms; she can now distinguish objects. At night, the pain in the eyes having returned, she was again bled to 12 ounces, with the same result.

8th.—She is free from pain; can see more clearly; pupils of natural size; part of the effused lymph absorbed; sclerotic nearly free from vascularity; gums are sore. In the evening the pain again returned, and she was once more bled to 12 ounces.

9th.—Sclerotic free from vascularity; has passed a comfortable night; left iris nearly restored to its natural brilliancy; sees pretty well; mouth very sore.

Omit the mercury.

10th.—The irides have nearly resumed their natural appearance; she sees perfectly; is properly salivated; cold perspiration, and nearly in a state of collapse.

Ordered Julep. Ammonia; wine and egg.

She soon rallied from her exhausted condition, and continued rapidly to improve. She remained in the hospital a short time longer for the eruption, when she was discharged cured. She has since married, and shewed herself a few days back at the hospital in perfect health.

In proceeding to make a few observations on the subject of syphilitic iritis generally, and on this case in particular, the author took occasion briefly to review the state of surgical opinion in regard to the question whether syphilitic iritis is to be considered a genuine secondary symptom of syphilis, as believed by Lawrence, Mackenzie, Carmichael, and many German authors; or as taught by Travers, Morgan, &c.—“that it is rarely unaccompanied or unpreceded by the symptoms called mercurial,” in other words, that “it is the result, not only of a venereal poison in the system, but also of the influence of mercury upon that poison.” Mr. Menzies was himself of the latter way of thinking, and stated it to be his conviction, founded upon the experience of the Eye Infirmary of Guy's Hospital, that “mercury is the flame which kindles the latent spark of venereal disease in the eye.” He next proceeded in the endeavour to establish certain diagnostic marks of distinction between syphilitic and other forms of iritis. These, he said, “generally consist in the distinct form which the lymph takes on; in the appearance and foxy or cinnamon colour of the zone around the cornea; and in the angular displacement of the pupil towards the root of the nose; together with nocturnal exacerbations of pain, and the appearance of secondary symptoms in other parts of the body. The local appearances are, however, a very imperfect guide to diagnosis, the constitutional symptoms being most to be depended on.” “The nocturnal exacerbations of pain are invariably present, and if the action of syphilis and mercury can be traced in the patient's system, that the disease is syphilitic iritis will seldom be an incorrect diagnosis.”

With regard to medical measures, Mr. Menzies vindicated a course of treatment of which that adopted in the case presented to night might be considered a fair type. He had no faith in turpentine for the cure of syphilitic iritis, whatever it might do in other forms of that disease; but under the tuition of his preceptor, Mr. Morgan, he felt unshaken confidence in large depletions and mercury, in the manner pursued in this case. The complication of retinitis, as evidenced by dilated pupil and palsied retina, rendered perhaps necessary a larger amount of depletion than might be required under other circumstances; but pretty extensive depletion was always useful, both by reducing inflammatory excitement *per se*, and in promoting the specific action of mercury upon the system.

Dr. Bossey could not agree in the opinion that mercury had any share necessarily in the production of syphilitic iritis.

Mr. Lawrence quoted a number of cases of that disease, in which mercury had been given in some quantity, for the cure of the primary sore in about one-third of the whole number; very little in about another third, and no mercury at all in the remaining third, and yet iritis supervened. Mr. Rose and Mr. Thomson had recorded, in the *Medico-Chirurgical Transactions*, the result of their trials to treat venereal disease without any mercury whatever: in some of these iritis followed. There were other facts of the same tendency in the *Edinburgh Medical and Chirurgical Journal*, and in other records, shewing incontestably that iritis may arise as a consequence of syphilis, although no mercurial action had prevailed in the system.

Mr. Hiff corroborated these views, by reference to the reports of cases preserved at Chatham, and the general records of military surgical practice.

Mr. Tweedie did not consider it proved that any distinctive characters appertained to syphilitic, which should entitle it to be considered different in nature from common iritis. In each case it was inflammation of the iris, whether of the muscular or fibrous structure (whichever it might be), or of the serous membrane covering it, he would hardly undertake to decide; and although the colour of the zone around the cornea was said to be different, it did not appear to be so invariably. The treatment, also, which was applicable to one, was equally adapted to the other complaint.

Mr. Carrington did not think syphilitic iritis was curable without mercury, at least he had never seen such an example; but other forms of iritis did not necessarily require that mineral.

Mr. Hilton adduced some interesting physiological observations, tending to establish a distinction between syphilitic and common iritis; but we were unable to follow the speaker with sufficient minuteness, and it would therefore be unjust to insert an imperfect statement of his views in this report.

The President disapproved of pushing depletion to so great an extent as had been prescribed by Mr. Menzies. In private practice he had known much mischief to follow; and he preferred relying upon mercury as his remedial agent.

A vote of thanks was passed to Mr. Menzies for his interesting communication.

The President now rose, and announced that this was the last meeting of the Physical Society for the present session. It was twenty-four years ago that he had attended on those benches as a pupil.

Since he had been in practice he had been a constant attendant at the meetings; and he must acknowledge that he derived both pleasure and much instruction from the papers and discussions which he had heard within these walls. He congratulated the members upon the extremely auspicious session now brought to a close, and trusted to meet them again next October, once more to resume their labours with equal profit and good fellowship towards one another.

The cordial thanks of the Society were presented to Mr. Harrison, the Treasurer of the Hospital, for the gratuitous accommodation he affords in enabling the meetings to take place free of expense, and to which all respectable practitioners find ready entrance—to the Presidents of the Society, Dr. Bright, Dr. Babington, Dr. Barlow, Mr. Cooper, Mr. Hilton, and Mr. Greenwood, for their kindness in presiding—and to the Honorary Secretaries, Dr. Rees and Mr. Tweedie, for their diligent attention to the duties which devolve upon them.

Thanks were also voted to the Chairman of the evening, and the meeting adjourned till the first Saturday in October.

The diploma, &c. of the Society, will be awarded at the annual adjudication of prizes to the pupils of Guy's Hospital, early in May.

This is the parent Medical Society of London, having been instituted in the year 1772, one year before the London Medical Society, now held in Bolt Court.

ON THE CORONER'S COURT.

To the Editor of the Medical Gazette.

SIR,

I am with real satisfaction, that after a perusal of Mr. Chatto's last letter, I feel called upon to state, that our difference of opinion as to the office of coroner appears so slight as hardly to justify further discussion; as, although the few remarks with which you are now troubled, may in some measure extend beyond those offered by Mr. Chatto, there will be found no radical difference in their tendency. I agree most perfectly with Mr. Chatto as to the inadequacy of the Coroner's Court as at present constituted, and more especially as to the scandalous system of picking up in the streets all sorts of men as jurors. It has been my lot, when serving the office, to preside over a jury, not more than three or four of whom could do more than substitute a X for his signature; nay more,

I have, as a witness, been examined before a coroner by a juror *so drunk* as not to know what I was saying to him, much less to understand it. The inquiry alluded to was on the 31st of March, 1828, and on the body of a child who died of marasmus, in the gaol here, to which at the time I was surgeon. Can a greater mockery of judicial investigation than this be required to satisfy the mind of man?

There is another subject connected with the coroner's inquest which ought to have some claim on public interest, as it involves considerable expenditure of public money—viz. the unnecessary inquiry in cases where death is manifestly the result of natural causes, or of mere accident. Is it necessary to harrow up the feelings of relatives already sufficiently grieved, by the public recapitulation of facts already but too well known; or to subject a body, under such circumstances, to mutilation (by which alone more can be elicited), where no suspicion of murder or self-destruction can by possibility be entertained? This is not an idle question, but one suggested to me by actual facts which have fallen under my own observation, and where there was no more necessity for inquiry than in a case of fever, cholera, or any other rapid and acute disease.

With your permission I shall now make a few remarks on the cases which appear to call for inquiry, and also the best mode, in my humble opinion, of conducting it when demanded.

1st. In regard to accidental death. Many of these cases are, no doubt, the effect of causes which no human ingenuity or precautionary measures could avert or counteract; whilst others arise either from very gross negligence on the part of individuals, or from still more flagrant causes.

2dly. As to sudden death. This may be the effect of disease, or it may be the consequence of violence, or of poison. Surely the same necessity does not exist in all of these cases. Yet we find, from a reference to the published reports of inquests, that verdicts of "Accidental death" and "Died by the visitation of God" infinitely surpass those of "Wilful murder" and "Manslaughter."

The cases of sudden death which justify inquiry, I conceive to be those only where suspicion exists as to the cause being the existence of an intention on the part of the deceased, or others, to destroy life; and in all such cases a medical, if not an anatomical, examination should be instituted. If wounds or other marks of violence exist, it then becomes a question whether they are self-inflicted or not. And even in the case of poisoning, it is of the

utmost consequence not only to determine the fact, but also, by collateral evidence, to prove whether it be the act of the murderer or the suicide; and, in the latter case, whether it be the act of the responsible being or of the maniac.

In cases of accident, the object should be to ascertain whether negligence, imprudence and rashness, or unavoidable circumstances, have produced death; and in cases only where these questions are actually doubtful should any inquiry be permitted. In illustration of the first may be mentioned all accidents in coal-mines, steam-boats, coaches, &c. The same may be said of the second, with some additions, embracing persons run over by impetuous riding and driving; too great application of steam by sea or land, &c.; shooting at marks in improper places, and so forth.

This outline, imperfect as it is, will I hope be deemed sufficient at once to prove the legitimate subjects of the coroner's inquiry, and also to demonstrate, by contradiction, the absurd though existing difference between what is and what ought to be.

In conclusion, I may state, that of late years (prior to the operation of the Municipal Reform Act) an attorney and a surgeon were associated in the office for this borough, which to me appeared a proper mode of bestowing the appointment, and likely to serve the ends of justice. This, however, is no longer the case. If the office of coroner be continued, it should, in my opinion, be thus divided. Although, at the same time, I must admit my conviction that it is a superfluous public expense; and in its stead, I would, with Mr. Chatto (imposing the duty of inquiry on the magistracy), suggest the propriety of appointing two medical men to examine into all suspicious cases, and to report thereon.—I have the honour to be, sir,

Your most obedient servant,
GEORGE FIFE, M.D.

22, Eldon Square,
Newcastle-upon-Tyne, April 22, 1839.

ON THE CORONERSHIP AND INQUESTS.

To the Editor of the Medical Gazette.

SIR,

So much has been said of late on the subject of coroners, that any further observations upon the subject may appear superfluous; and yet I am anxious to forward to you two or three cases of glaring mis-

management under the present system, because I believe there is a general impression abroad that some reformation is necessary, which impression will certainly augment with the increased exposure of the abuses which have so long existed.

I perfectly agree with you in thinking that the substitution of medical for legal coroners is the best remedy for the present evil, and therefore join with you in your opinion that Mr. Wakley's election to the coronership of Middlesex is likely to be beneficial both to the medical profession and the public in general; and I cannot but admire the candour you have shewn in giving such an opinion. Had I possessed a vote on the occasion, I should certainly have given it to Mr. Wakley, not because I believe him to be the best qualified medical man in the county for the office, as regards his knowledge of morbid anatomy and medical jurisprudence, which (I say it with due deference and respect to that gentleman) cannot, I should conceive, be very great, considering his numerous parliamentary and other avocations; but I should have voted for him as a precedent, and believing that from his medical and other acquirements he was likely to prove a far more efficient coroner for the county than any lawyer could possibly be. But to the cases, and they are briefly these: I of course mention no names, as I would not privately, much less publicly, say any thing to the injury of any member of the medical profession.

A gentleman was found on the road, near the town of —, weltering in his blood. He was carried home. Two medical men were sent for. Several blows had been inflicted on the head, one of which had cut through the scalp; and his medical men stated that they ascertained the skull to be fractured at this point; they alternately bled him to lower his pulse, and gave him brandy and other stimulants to raise it. He never spoke from the time of his being found, though he shewed evident signs of sensibility. No symptoms of compression arose; he died within four or five hours of his being found. No post-mortem examination was made. A stick was found in the possession of —, the knot of which so peculiarly fitted itself into the scalp-wound, that the jury and several other persons, amongst whom were the medical men, signed a declaration that it was their firm conviction that this stick had been the cause of death. On this and other corroborating evidence, two men were indicted for murder; the judge advised the jury not to find a bill; and two years after the murderer (neither of the

parties first suspected) was discovered: he confessed his guilt, and was executed; but the murder had been committed with a perfectly smooth-headed bludgeon—in fact, with an instrument for killing cattle. Of what did this poor gentleman die? Of compression of the brain? There were no symptoms of this.—Of concussion? Reaction had so far taken place as to induce the medical men to bleed.—Of inflammation of the brain? No symptoms of inflammation of the brain were mentioned, and this could hardly have taken place in so short a time!

As regards the fact of this poor gentleman having been murdered, neither a post-mortem examination nor an investigation into the subject by a clever medical coroner would perhaps have forwarded the views of justice; but such evidence might have been elicited as would have proved hardly less interesting than important to the public.

A gentleman suffering from what he considered rheumatic pains, applied to an eminent medical man in London for advice, who prescribed for him the iodide of potassium in dose of 6 or 8 grains (I forget which.) The gentleman sent his prescription to his usual medical attendant, who, having made up the medicine, called upon his patient to administer it. The patient was walking about (apparently to all in his usual health): he was sent for; and, upon swallowing a dose of the medicine, given by the medical attendant himself, exclaimed, "Good God! you've poisoned me! This medicine is too strong!" A relation tasted what remained in the glass, and expressed her opinion that it was very strong. The medical attendant put the other draughts in his pocket, saying he would dilute them, and left the house. Half an hour or so afterwards the patient was so extremely ill that two medical men were sent for. Before they could arrive (probably an hour or an hour and half) he was dead. From what was elicited as to the nature of his symptoms and the appearance of his body after death, there was at least a strong probability of his having been poisoned. At the coroner's inquest the medical gentleman who had administered the medicine was examined by the coroner: he brought with him the remainder of the draughts (as he stated, not yet diluted). Not even these were subjected to chemical analysis! No post-mortem examination was made! The coroner called another medical gentleman, to whom he put these questions, and these only:—"Do you believe eight grains of iodide of potassium are sufficient to cause death?"—"Do you believe twice that quantity sufficient to

cause death?" The coroner refused to give this medical witness the fee for attendance; stating, that he could only give one fee, which was due to the other medical witness—namely, the gentleman who had administered the medicine! The verdict returned was—"Died by the visitation of God."

A young woman died with every symptom, as far as could be ascertained, of having swallowed a corrosive mineral poison. She had formed an attachment, which was not unlikely to have preyed deeply on her spirits. The remains of a packet of arsenic were found in her bedroom. Cholera was prevalent at this time. The coroner called a medical witness; the only question he asked of him was—"Were —'s symptoms such as might have been caused by cholera?" No post-mortem examination was made, and a verdict was returned—"Died by the visitation of God."

I would crave your leave to make two more observations; the one is, that should the public be convinced of the propriety of selecting medical coroners, they will soon learn to take the trouble of selecting those who are best qualified. The other is, that there is one objection against medical coroners; namely, that they should not sit in those cases in which they have been professionally employed, which objection might be obviated by the employment of the coroner for a neighbouring district, in all such cases.

I must apologize for having taken up so much of your valuable space; but should my letter appear to you worthy of insertion, and should it tend in any way to rouse the attention of the medical profession and of the public to the necessity for electing more efficient coroners, it will gratify

Your very obedient servant,
A CONSTANT READER OF
THE GAZETTE.

London, April 20, 1839.

SUPPLY OF SUBJECTS IN GLASGOW.

To the Editor of the Medical Gazette.

SIR,

I ONLY yesterday observed, in your journal of the 6th, a leading article upon the inadequate supply of subjects, and the *clean* state (to use the *whaleships'* term) of the London dissecting-rooms. It occurred to me, that it would be interesting to you to know how we get on in this northern city, by the adoption of a plan precisely similar to that which you recommend.

We are not, as you may guess, much troubled with the visits of the inspector. Nevertheless, we get on exceedingly well, from having the countenance and support of the city magistracy. All the teachers requiring subjects—that is to say, those of anatomy and surgery, both private and in the University, amounting to eight in number—are associated with the magistrates and part of the city council, forming what is called the Anatomical Institution, acting under the legal advice of the city chamberlain. A meeting of this institution is held at the commencement of each session, and oftener, when required, and minutes of the proceedings are kept by the chamberlain. A purveyor is appointed, with a small salary, who has an office adjoining the Police Buildings, with a dead-room, and is provided with a hearse and proper servants.

In these of the parishes which have gone into the arrangement, when a person who has no relations dies in a lodging-house, or is found dead in the streets, or is dragged out of the river, the persons who have the custody of the body, on applying to the parish authorities for a coffin, are referred to the purveyor. He sends a coffin, and has the body removed to the dead-room, where it lies for two days, according to the act, in case of any one claiming it. If any friend wish to see it buried, it is then interred; if no one takes such an interest in it, it is sent to the dissecting-rooms in rotation. A regulation was at first made, that each teacher should receive three subjects for public demonstration, and should afterwards receive in proportion to the number of his dissecting pupils; but for the last three years the supply has been quite unlimited.

To defray the expense of the machinery, a price is paid by the teachers for each subject they receive. At first, this was three guineas; but the supply becoming greater, it is now only two for entire and one and a half for inspected bodies. This trifling charge has been found amply sufficient to meet all the expenses. Indeed, there is no doubt that the supply in this city is now the best in the united kingdom, with the exception, perhaps, of that in Dublin. Surely an arrangement of this kind could be gone into in London. Several purveyors might be appointed, and the result would certainly be satisfactory.

I am, sir,

Your obedient servant,

JAMES DOUGLAS,
Lecturer on Anatomy at the School
in College Street, Glasgow.

Glasgow, 22d April, 1839.

SLOUGHING AND DISCHARGE OF ABOUT TWENTY-FIVE INCHES OF LARGE INTESTINE.

AN example of this has been communicated to the Medical and Physical Society of Bombay, by Dr. P. Brown. It occurred in a trooper admitted into hospital, Nov. 20th 1834, with dysentery. The patient had almost constant calls to stool; the evacuations were scanty, very offensive, and passed with much straining; the abdomen was slightly tumid, with general tenderness on pressure, particularly on the left side; countenance anxious and palid; tongue slightly furred at the root and centre, with raw and reddish edges; stomach irritable; pulse soft and rather quick. These symptoms continued until the 20th Dec., when, while straining at stool, there came away a membranous tube about 25 inches in length, which on examination proved to be a portion of large intestine. This was of its natural calibre but its walls were much thickened; its three coats could be readily separated.

After the discharge of this portion of intestine, the evacuations, though still dysenteric, were passed without straining, and often involuntarily; gradually, however, they became less frequent, and the power of retaining them returned. The nausea and retching ceased, but the least increase in diet always proved prejudicial. January 18th, the appetite having become very keen, chicken was allowed; much irritation resulted, and though the former diet, bread and milk, was restored, still the patient continued restless and uneasy, but without any alarming symptoms till about an hour before he died, on the 20th, when he complained of excruciating pain in the abdomen.

On inspection after death, the small intestines were found so knotted together that they could not be traced: the large intestine was much shortened, and not a vestige of the sigmoid flexure existed. The rectum was much increased in capacity.—*American Journal of Medical Sciences.*

ENORMOUS DILATATION OF THE STOMACH

A remarkable example of this has been communicated to the Medical Society of Toulouse by M. Serian. It occurred in a man thirty six years of age, a great eater, and who selected for his food the most indigestible and drank the strongest liquors. He died of influenza. On examination after death, the stomach was found enormously distended, and occupying the whole abdomen; its form natural. The diameter of its great curvature was three feet two inches. It contained ten pounds of sanguineous fluid, its parietes were three lines thick.—*Ibid.*

MR. ESTLIN'S LETTERS ON VACCINATION.

THE readers of the GAZETTE are aware that Mr. Estlin, of Bristol, has communicated the results of his interesting and important investigations connected with vaccination, through the medium of this journal. We last week published our correspondent's "Fourth Letter"; but by mistake this was preceded by a communication intended to have been private, and which was headed, "Mr. Estlin's Third Letter," whereas his *third* letter was published in February. The mistake is attributable to the temporary illness of the gentleman who supervises the press, and to his deputy not having perceived that the letter in question was intended to be private.

It was our intention to have referred to the circumstance this week, even had we not received the following note from Mr. Estlin.

To the Editor of the Medical Gazette.

SIR,

On receiving, this morning, the last number of the MEDICAL GAZETTE, I was concerned to find that a private note I addressed to you on the 16th instant, written solely to bespeak space for the insertion of my "Fourth Letter on the New Vaccine Virus," has been printed in the GAZETTE, and headed "Mr. Estlin's Third Letter."

It is probable I may have omitted to write "private" upon that note; but the nature of its contents, and the hasty manner in which it was obviously written; seemed to render such an explanation unnecessary.

Many, I have no doubt, will perceive that the note could not be intended for the perusal of your readers, and will acquit me of the bad taste which writing such a one for publication would betray. To others, the subsequent letter will show that whatever private opinion I might hold respecting the National Vaccine Establishment, I have been anxious to avoid any disrespectful expression in what was meant for the public eye.

My "Third Letter" on the New Virus was published in your number for February 9th, 1839. If the present error be not corrected, confusion will arise from any future reference to that letter.

May I request that in the next number of the GAZETTE you will, as far as it is practicable, rectify the mistake which has occurred.—I am, sir,

Your obedient servant,

J. B. ESTLIN.

Bristol, April 29th, 1839.

MR. S. COOPER AND MR. LISTON.

To the Editor of the Medical Gazette.

SIR,

You will oblige me by inserting the following letter in the next number of your journal. The matter to which it relates will afford a pretty good illustration, in one party or another, of the truth of Terence's observation, "*Facile credimus quod volumus.*"—I am, sir,

Your obedient servant,
SAMUEL COOPER.

To Robert Liston, Esq.

Sir,—Some months ago, in University College Hospital, you cut into the bladder of a man named Fagan; and a piece of elastic gum catheter, incrustated with calcareous matter, was extracted. On this being shewn to the patient, who was yet on the operating table, he exclaimed, "Mr. Cooper did it;" and you immediately inquired of me whether I had done it. My reply was, that the patient could not possibly allude to me, for I had never attended him in my life; and he has since explained that the Mr. C. to whom he referred keeps an open shop in a very distant part of the town from my residence.

A report of this case, accompanied by your clinical observations, was inserted in the *Lancet* of the 20th instant, headed, "Mr. S. Cooper's Catheterism," and charging me in the text with having been the occasion of the accident.

Mr. Borthwick, who drew up the report from the hospital-book, declares that he delivered it into your hands for insertion in the above-mentioned *Lancet* publication; and that it then contained no allusion to any Mr. Cooper; consequently the false and slanderous insinuation must have been added to the document after it had gone out of his hands into yours.

As I disdain to say any thing behind a man's back which I would not say before his face, the opportunity is now taken of informing you that I have made the above particulars extensively known in the profession; and I sincerely hope that you will be able to satisfy the medical world of your not being implicated in this underhand and mean transaction. The pleasure that will be experienced by me, on your being able to convince the profession of your innocence in this affair, I assure you, sir, will not be diminished by the consideration that, in exculpating yourself, you must leave your friend, the well-known calumnious editor, deep in the mire, exposed so far as his head may be

out of the mud, to the contempt of all honourable minds.—I remain, sir,

Yours obediently,

SAMUEL COOPER.

LECTURES
ON THE
CHEMICAL HISTORY, PATHOLOGY, AND
MEDICAL TREATMENT
OF
CALCULUS,
AND THE VARIOUS DISORDERS OF THE
URINARY SYSTEM.

By DR. VENABLES.

Of Urinary Gravel and Calculi.

BEFORE entering into the pathological and chemical history of these affections, it seems necessary first to determine their composition and arrangement. The deposits from the urine, although consisting even of the same ingredients, assume a variety of forms, which probably may be conveniently referred, as it were, to three genera: these are the amorphous or pulverulent, the crystallized, and, lastly, the aggregation of these two into large solid concretions or calculi.

I. *Amorphous sediments.*—These sediments mostly consist of salts soluble in the urine, at the temperature when voided from the bladder; and hence they do not shew themselves, or become sensible, till the urine has been passed some time, and cooled, when they are precipitated as a fine powder, devoid of all crystalline appearance. They also vary in colour nearly as much as in form, and assume all shades, from perfectly white, like chalk, to deep brown, yellow, red, pink, or even purple. Nor is their composition less varied than their sensible and mechanical properties. Thus they are found to contain almost every principle, natural or morbid, existing in the urine, either itself capable of assuming the solid form, or of entering

into insoluble combination with any of the other principles. Those which are soluble at the temperature of the urine when passed, but which separate from it when it has cooled, for the most part consist of the lithic acid combined either with ammonia, soda, or lime; or an intermixture of these lithates combined with the purpurates, and tinged more or less deeply with the colouring matter of the urine. These constitute the lateritious and pink sediments. Another form consists principally of the earthy phosphates; that is, the phosphate of lime with the ammonio-phosphate of magnesia. These when alone are for the most part white. Of course, the latter, unless held in solution by some acid—as the hydrochloric, carbonic, or phosphoric—will be passed in mechanical suspension, only giving a degree of turbidity or opalescence to the urine. Frequently the lithates and phosphates are mixed together; but the lithates for the most part prevail; and it is to the little disposition which these have to crystallize that the pulverulent or amorphous form of these sediments is to be attributed. I here present you specimens of the amorphous kind.

II. *Crystallized sediments, usually named gravel.*—These sediments are for the most part voided with the urine in crystalline grains, and of an angular figure. What we have been considering above are generally deposited after the urine has been voided and arrived at the temperature of the surrounding medium; but the class under consideration are voided, in mechanical suspension, with the urine, and generally subside at the bottom of the utensil almost immediately the urine has been passed and is at rest. Sometimes, though more rarely, an additional crop of crystals deposits, as the urine at rest cools. Sometimes these crystals are wholly deposited after the urine has been voided, more passing with it, and then they appear abundantly.

dantly upon the surface of the urine, and upon the sides of the vessel in which the urine has been allowed to stand for some time. These crystals, according to Prout, consist—1st, of nearly pure lithic acid, with a little of the colouring matter of the urine; 2dly, of the phosphate of magnesia and ammonia; 3dly, oxalate of lime. In these two specimens, I present you instances of the two first varieties. With respect to the first, Berzelius maintains that they consist of the superlithate of ammonia; and generally ammoniac is recognizable on heating them with a little caustic potass. But Dr. Prout thinks this arises from a minute intermixture of the common lithate or purpurate of ammonia with which they are mostly, though slightly, contaminated.

The lithic* acid crystals—by far the most frequent variety—are generally of a red colour, more or less deep. I here shew you a specimen, and you observe various shades, from deep to pale red. The triple or ammonio-magnesian phosphate is white, and the oxalate of lime is of a dark green or blackish colour. Here you see crystals of the triple phosphate, and in this bottle you see the oxalate of lime; and for the opportunity of shewing you such a variety, as well as several others which I shall have occasion to shew you, I should be extremely remiss did I not acknowledge my obligation to Mr. Langstaff, who has most kindly permitted me to select whatever I thought proper from his most extensive and highly valuable museum. You, no doubt, naturally presume that these varieties of crystallized sediments are never voided together, as incompatible with each other, in the same urine; but the lithic acid and triple phosphate occasionally occur in the amorphous form, either mixed with each other or deposited after the urine has stood for some time. With respect to the mode of examining the chemical composition of these sediments, we shall consider this question under the head of *urinary calculi*. As calculi are found to consist of all these different principles, either simply and individually, or of two or more, or even all mixed together, it appears best calculated, to avoid repetition, to defer the mode of chemically examining the composition till considering the calculi themselves.

III. *Solid concretions, or urinary calculi*.—The different principles which we have been just considering, with others yet to be considered, when existing abundantly in the urine, and deposited by this fluid, aggregate into masses of greater or less magnitude, and then constitute what have been named *urinary calculi*, or

stones. From the number and qualities of the ingredients of which they are liable to be composed, it may naturally be presumed that they would present a great variety of appearances and of chemical composition.

Various classifications were at one time or other given of calculi; thus we had *renal, vesical, &c.*, divisions which, even if well founded, would be of no use in a pathological or therapeutical point of view. The chemical composition affords the only useful and valuable grounds of arrangement; I shall therefore now proceed to lay before you an enumeration of calculi, arranged upon this principle. The species of calculi at present known are as follows:—

1. Lithic acid calculus.
2. Lithate of ammonia calculus.
3. Oxalate of lime calculus.
4. Carbonate of lime calculus.
5. Phosphate of lime or bone-earth calculus.
6. Ammonio-phosphate of magnesia, or triple calculus.
7. The mixed phosphates, or fusible calculus, composed of a mixture of the phosphate of lime and the ammonio-phosphate of magnesia, or triple calculus.
8. Alternating calculus.
9. The mixed calculus.
10. Cystic oxide calculus.
11. Xanthic (lithic) oxide calculus.
12. Fibrinous calculus.
13. Prostatic calculus.

From the above it will be seen that the principal calculi, and those most frequently occurring, consist of the lithic, oxalic, and phosphoric acids, united to the bases ammonia, lime, and magnesia; that there is but one calculus of the above consisting of a single principle, the lithic. We shall now proceed to shew the characters by which each may be distinguished; and as the same method of analysis is applicable to the amorphous, as well as to the crystallized sediments found in the urine, it will be unnecessary further to particularize the methods of investigation. The characters by which calculi are determined may be, as in other instances, divided into sensible, mechanical, and chemical, although, perhaps, it will not always be necessary to adhere strictly to this order. However, before entering upon the analysis of the individual calculi, it may not be amiss to take a cursory view of their general properties; and first with regard to their sensible properties:—

Generally speaking, they have little or no smell unless heated; though when sawn through, they are said to exhale a urinous odour. They vary in colour often

* Often named *uric acid*.

according to their chemical composition, sometimes as they may happen to be tinged with animal matters—for instance, blood. Lithic calculi vary in colour, from a red to a mahogany or deep brown. Sometimes they present a fawn colour—instances of which I here present you. The phosphates are mostly white, or of a greyish colour, and friable. When white and crystalline, they consist of the triple phosphate; when friable, or softish, and pulverulent like chalk, they will be found to consist of the mixed phosphates or fusible calculus. Calculi which are of a very dark brown or black, and present a tuberculated appearance like a mulberry, mostly consist of oxalate of lime. But it should also be recollected, that lithic calculi sometimes assume a finely tuberculated appearance. You may here see a beautiful delineation of this variety in fig. 1, plate vi. of Dr. Marcet's work. There is also a calculus of tuberculated lithic acid; and if you compare the reality with the delineation, you will see how well it is represented.

In size, also, they vary as much. Sometimes they are small, not larger than a pea; while Sir James Earle describes an enormous calculus, extracted after death from the bladder of a patient who had been unsuccessfully cut for stone during life. This calculus is described as weighing three pounds four ounces; it was of an oval shape, and the periphery on the longer axis measured sixteen inches*. Calculi of such great size have been found to be mostly of the fusible kind. Here you see a variety of various sizes.

In density, too, they are very various: their specific gravity varies from 1.2 to 1.9, or 2.0, water taken as 1.0.

When sawn through, their structure is found to be various. Internally they are laminated or stratified. Sometimes they present internally an amorphous or earthy character; at other times they are very distinctly laminated, and often very hard and compact. Internally, also, they present nuclei; and the nucleus mostly consists of some of the species of calculi, and more especially lithic acid. In this fig. 2, plate 6, of Marcet's work, and indeed in this plate generally, you have very good representations of calculi with their internal nuclei. But in some instances the nuclei consist of foreign substances, as a pin, piece of cloth, fragment of a probe, or of a sound, or even a musket ball†; and in these cases the calculous deposit is found to consist of the earthy phosphates, and more particularly of the mixed or fusible.

In some instances they are found to

consist of concentric laminæ or layers, and these in one mass present all the varieties of calculous deposits. Thus, often the mulberry is covered with a white pulverulent crust of the earthy or mixed phosphates; and, indeed, present every variety in alternate layers: hence the name "alternating calculi."

The prostate gland is subject to an imbedding of very small calculi; they are generally of a yellowish brown colour, and rounded in their shape. In this plate ix. of Dr. Marcet's work, you have a good representation of them and of the gland. They are found mostly to consist of phosphate of lime. The presence of these bodies is, for the most part, connected with various changes of structure in the gland. We shall now proceed to determine the chemical composition of the individual calculi.

1. *The lithic acid calculus*, of which you here see several specimens, is of a reddish brown or fawn-colour, approaching, as it is said, that of mahogany. The surface is, for the most part, smooth; but sometimes, as in this specimen, finely tuberculated. Internally, it consists of concentric laminæ, well illustrated in this specimen. This fracture appears either imperfectly crystalline, amorphous, and sometimes earthy. In the latter case it is usually impure, containing a mixture of other substances. It is the most common of all calculi.

Chemical characters.—Heated before the blow-pipe it blackens, and for this purpose a forceps with platinum spoon-points are the best adapted. A small fragment about the size of a pin's head is placed, as you see, in one bowl, and confined by the other retained over it by means of the slide. On heating it a little it first blackens, emitting a peculiar animal odour, as you perceive, and ultimately dissipates, leaving a minute quantity of a whitish ash, and which, as you perceive, reddens moistened turmeric. Another character is, its complete solubility in the caustic potass; and from this solution it is precipitated as a white granular powder, as you here perceive, by the addition of a little acetic acid. Lastly, if on a small fragment, placed in a watch-glass we pour a drop or two of nitric acid, and apply but a very gentle heat, the lithic acid, as you see, dissolves with effervescence. On allowing the solution to evaporate to dryness, the residue assumes a pink or carmine colour, which, by the addition, of a drop or two of ammonia, is instantly changed to a beautiful purple.

2. *Lithate of ammonia calculus* is mostly of a slate or clay colour, the surface is sometimes smooth, sometimes tuberculated. Internally it consists of concentric

* Philosophical Transactions, 1809.

† Marcet on Calculous Disorders, p. 58.

lamina, the fracture very fine and earthy, resembling compact limestone. It is much more soluble than the lithic acid. This calculus is rather uncommon, generally of small size, and mostly confined to children under puberty. Here is a specimen, but with the particulars I am not acquainted. It often occurs mixed with the oxalate of lime, forming a variety of mixed calculus.

Chemical characters.—This, as might naturally be expected, presents many characters in common with the last described calculus, lithic acid. Heated before the blow-pipe it crackles or decrepitates strongly. It is soluble in a much less quantity of hot water than the lithic acid; and if heated with caustic potass, the ammonia evolved is sensible by its pungent odour; and by the effect upon moistened turmeric paper, or reddened litmus paper, and held in the escaping gas—as you may here observe. Lastly, it may be further distinguished from the lithic acid, the only principle with which it is likely to be confounded, by the ease with which it may be dissolved by digestion in a solution of the carbonates of the finer alkalies (potass, for instance), which the pure lithic acid is not. The theory of this is very obvious: the lithic acid will not, by the exertion of single electric affinity, displace the carbonic, but rather gives place to the latter, as you have already seen. But when we make the case one of double elective affinity, an exchange of principles takes place; the carbonic acid of the potass passes to the ammonia, forming carbonate of ammonia, and the lithic acid unites to the potass, forming lithate of potass—two salts sufficiently soluble.

3. *Oxalate of lime*, usually named *mulberry calculus*, from its external appearance. It is generally of a very dark brown or black colour. It has a rough tuberculated appearance, very much resembling the mulberry fruit, whence its name. It is very hard and compact, and when sawn through presents an imperfectly laminated structure. It seldom surpasses the medium size, and is by no means uncommon. Here you see several specimens, which bear out the description given of the sensible characters. In this bottle you see a large collection of a variety of this calculus, and for which I am indebted to Mr. Langstaff. As you may observe, they are small in size, of a darkish colour, and very smooth, and resembling the hemp seed; whence they have been named *hemp-seed calculi*. This variety mostly contains lithate of ammonia, with which principle the oxalate of lime is found mixed, and in every proportion; and the characters in a great measure depend upon the predominance of either principle.

Chemical characters.—Exposed to the blow pipe flame, this calculus first blackens, swells out, and expands into a kind of white efflorescence. This depends upon the decomposition of the oxalic acid, which is converted into carbonic; and if the heat be continued, is ultimately driven off, and the white ash which remains behind is alkaline, and reddens moistened turmeric paper. This ash is the caustic or quick-lime, deprived of its oxalic acid. These characters would be sufficient, generally speaking, to distinguish this substance, but when we wish to see more perfectly the constituents, we may proceed as follows:—A portion of the oxalate reduced to very fine powder, is to be boiled for a considerable time in a solution of carbonate of potass. By long digestion, an exchange of principles is effected, attended with the formation of carbonate of lime, which is insoluble, and oxalate of potass, which is dissolved in the water. The oxalic acid now in solution may be readily identified by the application of chloride of calcium, sulphate of copper, and nitrate of silver. This precipitate from this last is extremely characteristic, from the property which the oxalate of silver has of detonating feebly when dried and heated. These properties we shall now proceed to exemplify.

4. *Carbonate of lime calculus*.—This species of calculus is very uncommon. Dr. Prout states that he “has seen some small calculi composed almost entirely of this salt. They were perfectly white, and very friable*.” Mr. Smith also described others which very much resembled mulberry calculi†. However, they are not very frequent. Mr. Brande states that in several hundred calculi which he examined he never met with it from the human bladder. He further states, that he observed very small and perfectly spherical concretions, composed of carbonate of lime and animal matter, voided in a case in which they apparently come from the prostate gland. In the Journal of the Royal Institution I have related the particulars of a case in which small concretions of carbonate of lime were passed by the individual.

Chemical characters.—Before the blow-pipe they are rendered caustic by the dissipation of their acid. They readily dissolve with effervescence, on adding almost any acid. When the fragment is very small, I generally introduce it into a small tube containing a stratum of acetic or hydrochloric acid confined by mercury. The tube thus arranged—as you see in this instance—is inverted in a small cup of mer-

* On the Urinary Organs, &c. p. 93.

† Med.-Chirurg. Transact. vol. xi. p. 14.

cury, and the fragment introduced rises to the surface of the mercury—as you see—and is immediately acted on by the acid. The carbonic acid disengaged is confined by the mercury, and of course can easily be examined.

5. *Phosphate of lime, or bone-earth calculus.*—Phosphate of lime forms very frequently a constituent of calculi; still urinary calculi, consisting wholly of phosphate of lime, are probably very rare. Concretions consisting entirely of phosphate of lime have been satisfactorily proved by Dr. Wollaston, who gives the following summary of their sensible and mechanical properties:—"Its surface is generally of a pale brown, and so smooth as to appear polished. When sawn through, it is found very regularly laminated, and the laminae in general adhere so slightly to each other, as to separate with ease into concentric crusts. In a specimen with which I was favoured by Dr. Baillie, each lamina is striated in a direction perpendicular to the surface, as from an assemblage of fibres*." In this specimen you see all these characters well exemplified. Externally it is of a pale brown, and the surface has a smooth appearance, somewhat like porcelain, to which it has been not inaptly compared. Internally, as you observe, it is laminated, and the laminae striated in a direction perpendicular to the surface. In plate viii. fig. 7, of Dr. Marcet's work †, we have a very well characterized fragment of this species of calculus, which I here present to you.

Chemical characters.—Before the blowpipe this calculus first becomes black, in consequence of the charring of the animal matter; but as the heat is continued, it becomes perfectly white again, and resists any further action of the blowpipe; unless, indeed, a very intense heat be excited (and such as few persons can raise), when it may at last be melted. This susceptibility of fusion distinguishes the phosphate of lime in calculi from that in bones, the latter containing more lime in its composition than the phosphate of calculi. The ash which remains is neither acidulous nor alkaline—characters which will distinguish the phosphate from the carbonate and oxalate, which leave an alkaline ash. Further, it is soluble in the hydrochloric and nitric acids, from which it is precipitable again in the form of a white powder unaltered, by neutralizing the acid by means of an alkali. To verify more perfectly the constitution, we may proceed as follows:—

Boil the calculus, finely pulverized, in a solution of carbonate of potass. By con-

tinuing the digestion for a sufficient length of time, an interchange of principles takes place, with the formation of insoluble carbonate of lime, and phosphate of potass, which remains in solution, and may now be recognised by the tests already mentioned in a former part of these lectures, and which it would now be unnecessary to repeat. The insoluble part may be digested in very weak acetic acid, which will expel the carbonic acid, and acetate of lime will be in solution, and may be determined by the agency of oxalic acid and other well-known properties. There are several other methods of identifying phosphoric acid; but it is quite unnecessary to consider them, the blowpipe analysis being perfectly sufficient for all practical purposes.

LECTURES

ON THE

VENEREAL DISEASE,

Delivered at the Aldersgate School of Medicine,
March 1839,

By F. C. SKEY, F.R.S. &c.

Sketch of the history—Three primary forms of venereal disease—Disease often of spontaneous origin—Forms of sore dependent on constitutional peculiarities—Plurality of poisons—Various kinds of sore probably modifications of each other—The Hunterian chancre—The claims of Mr. Hunter as an authority in the venereal disease of the present day—Necessity of a clear definition of the terms "induration," "circumscribed thickening," &c.—Rarity of the indurated sore.

In the ensuing lectures on the Venereal Disease, I shall endeavour to place before you a general view of this involved subject, simplifying it as much as possible, and introducing matters of collateral interest only in as far as they tend to elucidate the subject under consideration.

There is a long history appended to it, into which, however, I shall not enter unnecessarily. The general belief prevails, that the venereal disease was unknown in Europe before the close of the fifteenth century. In the year 1494, it is reported by the Spanish historians of that date to have been introduced into the peninsula from St. Domingo, and other islands of the West Indies, by the Spanish sailors who attended Christopher Columbus and his brother Bartholomew, in their several expeditions of discovery; that it was communicated to the French troops at Naples by the Spaniards, and was by them conveyed to France, and named the "morbus

* Philosoph. Transact. 1797.

† See also Prout, figs. 15, 16, and 17.

Gallicus," previous to which it was well known in Spain under the name of "las bubas" (whence possibly our name bubo.) The glory attendant on the successful issue of the French expedition, for a time reconciled the people to the opprobrious name of their new acquisition, though they ere long became captious and sensitive to the indignity; they named it, and not unreasonably, "le mal de Naples." As it extended through the various countries of Europe and Western Asia, it took invariably the name of the country through which it travelled. The English called it the French disease, as did the Germans; the Poles knew it under the designation of the disease of the Germans; the Russians, the disease of the Poles; the Persians and Turks, as the disease of the Franks. "At length," says Astruc, "the French physicians became ashamed of the infamy which was grown so common, and thought themselves engaged to throw off the scandal which had been unjustly thrown on their country, and by common consent it was named the venereal disease."

The venereal disease, naturally acquired, may exhibit itself in three distinct primary forms:—

1st. As a discharge of purulent matter from the urethra.

2d. As an ulcer. And—

3d. As an induration of the subcutaneous or submucous-cutaneous cellular membrane, succeeded by ulceration.

Of these, the two former are of most frequent occurrence.

Besides these, the genital organs are the seat of sundry varieties of disease strongly resembling the venereal, from which it is often most difficult to distinguish them.

Before I proceed to the immediate subject of the disease itself, I wish to introduce some points of interest for your attentive consideration.

It is a common opinion that the form of the affection developed by sexual intercourse, corresponds with that of the party by, or from whom, it has been produced; and also, that this disease is the product of a specific poison. There is, as it appears to me, abundant evidence to the contrary; to prove which I need not, for my own satisfaction, travel out of the record of my own recollection. One of the most credible authors on this subject, an army surgeon, states, "I have been present at the public examination of 200 women of the town, and most frequented by soldiers, and not one case of disease was found; nevertheless, the hospitals continued to have the usual number of venereal cases. Subsequently 100 were examined, and only two were diseased; and the author most justly remarks, "It

is impossible that these two women could have infected the whole garrison"—an opinion that I presume will admit of no altercation.

Now, either the disease in these women existed beyond the surface exposed—a supposition at variance with every day's experience—or the above facts are false; or the diseases under which these men were labouring, were spontaneous, or at least self-generated; and if self-generated, I do not see why I am compelled to place an unqualified faith in the history given by Astruc and others, of the introduction of the venereal disease in the fifteenth century, because if these maladies be susceptible of an origin independent of specific contagion, it is clear that they may have been similarly produced at any period in history.

The term self-generated (I will not say spontaneous, for that is still more objectionable) expresses something short of the idea I wish to convey. I mean that, in a certain condition of constitution, the elements of a poison lie dormant, which may be developed by the action of a simple irritant, and that that irritant may exist in the form of any apparently simple, but unhealthy exciting cause in the female, such as leucorrhœa, menstrual fluid, or indeed any impure secretion of a puriform character; and may also be developed by mechanical irritation.

I do not say that the venereal disease is invariably propagated by these means, because there is plenty of experience to the contrary; but looking, first, to the frequency of disease, whether ulcerative or catarrhal, obtained by intercourse with women, without ground for suspicion of disease; secondly, to the liability of each individual to the formation of the same description of sore (one man, says Mr. Evans, will have a succession of attacks of gonorrhœa, another of simple venereal sores, which, in a third, as invariably assume a phagedænic character); and thirdly, to the existence of a form of ulcer (the true syphilitic), which is characterized by induration, often even without abrasion of the surface; looking to these and various other minor grounds for this belief, I cannot myself entertain a doubt but that primary venereal disease of each and every kind may be developed after sexual intercourse, without the presence of venereal disease in the female of any kind. One of the worst cases of gonorrhœa I ever prescribed for occurred in the person of a youth who seduced a young lady residing in the same house. There was not up to that event the slightest ground of suspicion against her, but, on the contrary, every confirming circumstance of her previous purity; and, as regards the youth

himself, it was notorious in his family circle that he had "never sinned."

I may be told that his disease resembled gonorrhœa. I assert that it was gonorrhœa; and if profuse discharge, first of pus and then of blood, great ardor urinae, severe chordee, irritation of the bladder, constitutional fever, the product of the local cause, a persistence in the above symptoms during a period of two months, and a gleet discharge occupying two months longer, if such be not a sufficient test of gonorrhœa, it were perfectly absurd to pretend to any power of discrimination; and who can doubt but that this disease was communicable? You will also observe, that the gentleman alone had the disease, from which the other party was entirely free! And let me ask, in what respect, however minute, does this disease fall short of gonorrhœa obtained by promiscuous intercourse, and under which circumstances, indeed, I am persuaded it is frequently acquired, where no disease exists.

I had, some months since, under my care, a gentleman who had an excoriation, for which, at the suggestion of his medical attendant, he employed mercury in considerable quantity. The excoriation healed entirely, and the mercury was discontinued. Ten days afterwards, during which interval he had no intercourse with woman, "fair or foul," a phagedænic, and rapidly-extending sore, broke out in the neighbourhood of the former excoriation, but not upon the original surface. Now this sore (which I saw from its birth, or at least too early to possess the title to a name,) when consequent on contagion, appears between three and five days after it. Upwards of a month had elapsed from the date of the former connexion, and ten days from the healing of the excoriation. Could this sore, then, be the product of specific poison obtained by contagion? Undoubtedly not. This gentleman had the aspect and the pulse of a remarkably sensitive man; his pulse rose or fell ten or fifteen beats, according to the exciting or tranquillizing tendency of the conversation. His appetite was readily disturbed by mental emotion of any kind; his bowels naturally and habitually regular, while his nervous system remained undisturbed, became irregular in a marked degree on any deviation from his daily habits; his face was pallid or flushed half a dozen times during the quarter of an hour of each medical visit. This gentleman had taken mercury to salivation. Can you doubt that his constitution generated its own sore? And yet this identical sore, if not arrested by treatment, would probably lead to secondary disease

of the very worst, the most destructive, and the most intractable kind.

There is one obvious and easy mode of disposing of the question, by those who dissent from this view of it; and that is, to question the veracity of the parties involved in the inquiry—to erect in our own minds an arbitrary standard of truth, and to start with the resolution that no testimony shall shake it. If the statement of a guileless patient, applying, under circumstances of great pain and greater apprehension, for our professional aid, do not correspond with these views, we must drive him to confession by any little devices our ingenuity may suggest for its attainment; and in this we do but follow in the path of other honourable men whose professional sagacity, as it has always appeared to me, is singularly prostituted, in the attempt, by cross-examination, to obtain a confirmation of their party view, and to pervert in a large number of instances the current of truth and justice.

There are few, very few men, whether educated or not, who can stand the test of a minute and searching cross examination in the presence of many observers. This system may doubtless often tend to expose falsehood, but I have a very strong impression that it does not very frequently promote the cause of truth.

With regard to the malady under consideration, it is a singular fact that disease should exhibit itself in the form of a single sore only. Supposing a woman to be the subject of a primary sore, one would suppose that the secretion of that sore would be diffused pretty generally over the surrounding muco-cutaneous surface of the vagina. Why, then, should this specific virus exhibit its influence by contaminating one spot only, and not various spots? for although we occasionally meet with what are called a *crop of sores*, they are rarely primary, but are the result of contamination from the original affection. It is certainly no very satisfactory solution to be answered that the virus remained in contact with that surface and not with others, because we should suppose each part of the exposed surface subject to the same exciting cause, or by ablu-tion equally placed beyond the pale of its influence. Why, then, should the noxious matter exhibit its baneful consequences on one only? That the presence of a sore does not engage the entire attention of the parts ordinarily the seat of disease, may be inferred from the liability to contamination from a primary sore by the neighbouring parts, as in the matter of a common sore, or the frequent formation of a common venerola, during the pro-

gress of gonorrhœa. This fact appears to me rather to favour the view of the self-generation of sores, although, perhaps, not to any considerable extent, inasmuch as that a large proportion of sores occur on those surfaces of the male organ on which contagious matter would be more likely to be retained after connexion.

The difficulty, however, still remains unexplained why we have not generally a plurality of sores, supposing them to be obtained by the application of contagious matter during connexion. I have often asked myself the value of all the information that is in being, tending to prove the fallacy of these views. How often during the career of any eminent practitioner has he had opportunities of determining the communication of the same poison from one party to another? Evidence of disease having been communicated is one point, but the identity of that disease in the two parties is another.

And this leads me to another question, perhaps more of pathological than of surgical interest; I mean the extensive question of the plurality of poisons.

Many authorities favour the opinion that there exists not one poison of a specific venereal kind, but several; that each is attended by its own distinct characters and symptoms; and that this holds true not only as regards the primary affection, whatever form it may assume, but also of its constitutional or secondary forms.

The opinion is founded on the belief that a certain uniform series of secondary symptoms is consequent on each distinct form of primary disease. It is strengthened by the dissimilar forms of treatment required for each affection; some being supposed curable by mercury alone, while others yield to simple remedies, in which mercury is not only unnecessary but injurious; one form of poison, again, invariably attacking one structure only, this structure being insusceptible of contamination from others.

The great authority of the present day is Sir R. Carmichael, who has systematized the subject, and divided these morbid poisons into four, which he determines, not by their primary character, but by their remote influence on the constitution in the production of eruptive and other diseases.

Those who entertain the opinion that the whole train of venereal symptoms, both primary and secondary, are the product of the same poison, refer the variety in appearance to the different forms of organization of the affected parts, and to the modifying influence of health, temperament, and climate. In support of this doctrine, we have sundry modern authors of repute, and for the most part the military surgeons, who have contributed so

largely and so valuably to the records of surgery in reference to these maladies.

The advocates of this doctrine dissent from the opinion that a particular form of eruption or sore throat, follows any given character of primary sore, asserting that in one case one form of eruption, whether scaly or pustular—that in another, whether pustular, tubercular, or even two or three intermingled—shall characterize the introduction of the same poison into the constitution.

The admitted existence of a venereal disease prior to the end of the 15th century, may be applied as a conclusive argument in favour of the doctrine of a plurality of poisons, by those who rely on the evidence adduced in favour of the introduction at that date of a morbus gallicus; but it must be acknowledged, in relation to the latter disease, that its characters and general symptoms at the present day, supposing the two to be identical, correspond but imperfectly with those detailed by the writers of the 16th century—viz. the date succeeding to that of its supposed introduction; and the question may with great reason be asked, whether this latter disease be now extant? Among other authorities quoted by Astruc in proof of the recent introduction of the venereal disease into Europe, is that of Roderic Diaz, a physician of Seville, in 1550, who says—"It took its origin from the island of Hispaniola, as has been found by long and certain experience; for when that island was discovered by C. Columbus, the disease being infectious was easily communicated to the soldiers, and soon spread throughout the army; and as at the same time that Columbus the admiral arrived, the Catholic king, to whom he gave an account of his voyage, resided at Barcelona, immediately the whole city began to be seized with the same disease, which spread itself quite over it." Indeed, the numerous accounts given of it by Spanish, French, and Italian authors, at the date of its importation, characterize it in terms which convey in this day the idea of a disease more offensive and more dreadful than the plague itself. A German author of 1496, three years subsequent to its introduction, says, "it was a disease sent down from the citadel of the immortal gods on the French—a most horrid and terrible prodigy, unheard of, hated, and unknown—a disease repugnant to nature." Again, another German author (1532) speaks of it as "a destructive disease. The poor people that laboured under it were thrown out from human society, and deserted by the physicians. They were obliged to live in the fields and woods."

Gabriel Fallopius says, "there was

found the most precious gold, and plenty of it was brought from thence, together with abundance of pearls, but there was also a thorn joined to the rose, and aloes mixed with the honey; for Columbus brought back his vessels laden with the French disease! There, in Hispaniola, the disease is mild, and like the itch among us; but transported, it has become so fierce and so unmerciful as to infect and corrupt the head, eyes, nose, palate, skin, flesh, bones, ligaments, and at last to corrupt the whole bowels."

For myself, I must plead ignorance of this "terrible prodigy." I cannot see the likeness to any form of this disease now extant, and surely it is not very unreasonable to suppose that, with the unhappy victims of its former virulence, it has long since slumbered with the dead.

I doubt not you will concur with me in the belief that this question is surrounded with difficulties of no ordinary kind. We have, on the one hand, the numerous contributions of the authors of the 16th century, who positively declare in the absolute novelty of the disease; all of whom concur in opinion, on the subject of its introduction by Columbus, in the year 1493. We have, moreover, the authority of Carmichael and Abernethy, and other authors of repute,¹ in favour of the opinion that particular forms of eruption are consequent on certain varieties of primary disease—an opinion with which, to a great extent, I fully concur; while, on the other hand, we have the declaration of Messrs. Guthrie, Hennen, Cooper, and Bacot, that "no peculiar secondary symptoms are seen to follow from peculiar primary sores," (inferring, I presume, that one and the same poison exists in every form,) and the expressed declaration in favour of the identity of poison in every form of primary venereal affection, by Mr. Travers, Mr. Wallace, and Mr. Colles.

I find primary disease, not however invariably, followed by particular forms or groups of secondary affections, but by no means with the uniformity of order described by Sir R. Carmichael; to whom, however, I think we owe a great debt of gratitude. I cannot reconcile it to my mind to consider a form of primary sore which is under no circumstances the precursor and cause of secondary eruption, identical with another sore, which, unless means be taken to check it, almost necessarily leads to sore throat, eruptions on the skin, pains in the bones, and extensive disorganization of structure; or that a poison causing deposition, as its most striking characteristic, can be identical with another, marked by ulceration merely.

But I shall not dwell on this subject

longer, as I do not see that it can lead to any practical results; for whatever be the views taken by the advocates of each opinion, it is probable that the treatment of the diseases in question will be governed only by the symptoms immediately developed by them.

It is highly probably that the venereal poisons if not identical, are at least not very dissimilar, and that they may be classed under the relationship of modifications of the same poison, owing their distinctions in a greater degree to the constitution generating or communicating them, than to any primary or original property they may possess, in the person of the individual affected; for I am strongly of opinion, that if the germ of what would be deemed a well-marked disease, were communicated throughout a circle (suppose of twenty persons, each of whom should be alone subject to the infection of the person first contaminated), we should have no difficulty in tracing, within a brief period of time, the extension of venereal affections of each and every description; and that the poison of this one sore, transmitted through a variety of constitutions, would develop itself in one individual under one character, and in another under a totally dissimilar one.

Again, if the variety of sores be the product of totally different poisons, and if they be not greatly modified by the constitution of the person affected, is it not singular that we rarely, perhaps never, see two or more descriptions of sore; congregating in the same individual more especially when we consider the liabilities to contagion, from every form of venereal poison, to which the lower class of prostitutes are exposed; and would it not appear from this that the constitution of the individual exerts a most important influence in determining the form that ultimately exhibits itself?

Mr. Hunter's volume on the Venereal Disease was published in the year 1786; and considering the confused and ill-digested mass of knowledge that prevailed on that subject, up to the period of its publication, we cannot be surprised at the overwhelming influence it acquired, and the profound deference paid to its authority by the surgical world. Its merits are his own; its defects are based on the obscurities of the subject itself, which it is evident no single mind could entirely illumine.

You will think it strange, if, acknowledging as I do, the exalted merit of this production of Mr. Hunter, I express my honest belief that it has been the means of perpetuating more error than any book of authority ever published on a medical

subject, but to which the author's high reputation has more contributed than the author himself. Mr. Hunter's book gives general and enlarged views on the history and development of the venereal disease, and of its consequences, but he has passed entirely unnoticed the great variety of primary, as well as secondary diseases, which are incidental to it. Perhaps this is not surprising, when we recollect the important advances which surgical as well as physiological science have made since the publication of his work. However, we have all heard of the Hunterian chancre, the name of which has been in the mouth of every surgical teacher for the last quarter of a century, both British and continental,—a marvellous illustration of the influence of authority.

Probably, then, I shall surprise you if I state most unequivocally, that Mr. Hunter never described a chancre, if by the term described is understood the delineating all the important characters by which it is marked, although in the elaborate work of M. Rayer on Cutaneous Diseases the author has actually delineated one, under the title of the Hunterian chancre. Authors and lecturers delight in referring to the admirable definition of a chancre by Mr. H., which they say will neither admit the addition nor the subtraction of a word. When I say Mr. Hunter has not described a chancre, I do not wish you to suppose that he has passed over the subject in total silence; but I mean to assert, and that deliberately, that the very meagre and superficial account which he has given of chancre, is totally inapplicable to the variety of sores we daily meet with, and as regards diagnosis, almost useless in practice.

There is on the subject either the most wilful perversion or the most extraordinary self-delusion prevailing in the profession, that any learned body could well be the subjects of. A certain description has been given, embracing one single characteristic of chancre, and one only, out of many; the entire picture of which has been completed by the fancy of his followers. Moreover, the cursory and brief outline in which Mr. Hunter has sketched the disease conveys the idea that he was familiar with no other form of sore with which to confound it. It is rather adverted to, than described, in words to this precise effect—an ulcer with a base of circumscribed hardness and prominent edges. Now, if you ask a surgeon to describe the “true Hunterian,” he will say, “an ulcer with a hard base,” to which is often added, “having thick white matter adhering to it, like a slough, which cannot be washed away; the addition being forcibly and unwarrantably purloined from the description of the venereal ulcer of the tonsil by the same eminent

author. There is no allusion to its form—whether flat, excavated, or prominent—to its varying degree of hardness in different localities, nor to its duration. Now it is this same induration of the base, this circumscribed thickening, forming, as it does, the prominent character of the description, and in the mouth of every practitioner, that I want to see and understand. In the first place, what is meant by circumscribed thickening? In order to explain it I must observe that all forms of ulcer that progress slowly exhibit the effects of a greater or less degree of deposition of lymph around their circumference, giving a degree of firmness and of form to the ulcer proportionate to their torpidity of action. This applies not only to venereal, but, in a more striking degree, to almost every other variety of sore. Contrast a rapidly-ulcerating or phagedænic sore with any other form that has been long under treatment. I do not say that all chronic sores are hard, but that all hard sores are chronic. This hardness is solid, as the term would denote, and would be ill expressed either by the term “swelling,” or “tumefaction,” or puffiness.

There can be no doubt of the existence of “hardness,” when present. It is palpable to the touch, and almost evident to the eye; and when really present no one will hesitate for a moment in acknowledging it. There may be a difference of opinion, however, when it is not.

Now, whenever induration is a character of venereal, or indeed of any other form of sore, the general ulcerative action is peculiarly slow: I say the “general ulcerative” action, because any sore may, under circumstances of peculiar excitement, assume a new disposition, and ulcerate with great rapidity.

The consequence of this slowly-advancing action is, that such sores extend by ulceration to the surface of the induration merely; they are generally flat, and rarely hollowed or cup-shaped. To imagine an induration excavated by active ulceration into a sore, would be a glaring error in pathology, for we cannot suppose that nature would establish two actions so diametrically opposed at one and the same time. I do not deny that a cup-shaped sore may be surrounded by tumefaction, for such condition is a most common consequence of ulcerative action, but that it is never surrounded by absolute induration—the circumscribed thickening of Mr. Hunter's description.

As a general rule we may infer, that whenever ulceration is coupled with thickness or hardness, the latter precedes in the relation of a proximate cause, the ulceration being the effect; when coupled with treatment of venereal sores, excepting the sore accompanied by the circumscribed

tumefaction merely, the ulcer precedes, of which the tumefaction is the effect, or at least the sequence.

But to what, you may ask, does all this tend. It tends to this, that the chancre of the present day is not the form of disease described by Mr. Hunter in the year 1786.

Examine for yourselves. Form your own opinions on an unprejudiced examination of a variety of cases.

During the last three years of the life of my lamented friend Mr. Earle, I had under my charge his three venereal wards in St. Bartholomew's Hospital, and I am confident that induration was not present in a twentieth part of the many hundred cases I treated during that period; I mean the induration which, to retain Mr. Hunter's own words, being "very circumscribed, does not diffuse itself gradually and imperceptibly into the surrounding parts, but terminates rather abruptly."

But of more than a hundred cases I have examined during the last three months, of venereal sores, *three only exhibited induration*. If the description of the peculiar thickening were not occasionally seen, we might almost doubt the terms of the definition, but it is seen, and known, and cannot be mistaken by the most superficial observer. Either, then, Mr. Hunter failed in his observation, or he failed in his description, or finally, the sore which bears his name has almost ceased to exist. One of these three positions is inevitable. No one has apparently felt this difficulty more than the annotator of the late edition of Mr. Hunter's work on the Venereal Disease, between whom and the author, if I am not greatly mistaken, there appear some remarkable discrepancies of opinion evidently expressed under the half concealed desire to reconcile the differences that really exist between them. The fact I believe to be, that the annotator is too close an observer, to be implicitly and entirely led, or rather misled, by Mr. Hunter; and as far as it could be effected, he has succeeded in blending two forms of sores, which are in character evidently very dissimilar. He says, "the author's (Mr. H.) description applies to a large majority of cases of primary venereal sores." Did this description of Mr. Hunter's apply at the date of his publication to a *majority* of primary venereal sores only, and not to the whole? If so, is it not passing strange that Mr. Hunter himself should not have said so? Was this the only form of sore that flourished at the date of Mr. H.'s observation?

The annotator continues:—"Two consequences follow the application of the venereal virus—induration and ulceration,

and these seem to be distinct and independent, since, though they generally exist in conjunction, they are sometimes found separate, one or the other of them being in some cases wanting." After asserting the more uniform constancy of the induration than the ulceration, (a position I strenuously deny) the annotator observes, "the thickening precedes the ulceration, the first effect of venereal contamination, being the production of this peculiar change in the structure of the parts. The second effect, to produce ulceration of the indurated portion. The primary character of venereal infection is essentially induration, passing afterwards into ulceration." Again, "in the earliest stage of the existence of a chancre this sequence is least discernible, there being frequently at that period superficial and incipient ulceration, with very little apparent thickening." Now Mr. Hunter says nothing of frequently existing ulceration preceding the induration. He says, the first appearance of the sore on the prepuce is, in some cases, excoriated, and afterwards ulcerated; in others, a small pimple occurs or abscess appears, as on the glans, which forms an ulcer, a thickening of the part comes on," &c. I think I may venture to state to you that the indurated sore *does not commence as a pustule at all*, or if it do that it holds no relation to the local form of disease when fully developed. I agree with the annotator, and not with the author: the former says, and says truly, the thickening in general precedes the ulceration; but this observation will only apply to the rare form of disease described by Mr. Hunter. What is the crisis of the pustule? does its career terminate in resolution? does it die a natural death in order to give a temporary independence to the induration? Is the induration to the pustule what the pupa is to the larva of insects? Will the annotator of Mr. Hunter's work on the Venereal Disease, highly competent as he has proved himself to that task, will he undertake to assert that he has ever seen circumscribed induration succeed to a pustule?

However, the question is, is the circumscribed thickening described by Mr. Hunter an usual attendant on venereal sores, or is it not? I believe it is not; and if you traverse the foul wards attached to every hospital in this metropolis, you will not find the Hunterian circumscribed induration present in the proportion of one case in every 20 primary venereal sores. This form of the disease is the most rare of all forms. Mr. Evans, whose excellent work on the diseases of the genital organs I strongly recommend to your study and perusal, has given the most impartial and simple account of the origin, progress, and

induration of Mr. Hunter. He states that the common primary venereal sore is, in a very large ratio, the most common of all venereal ulcers. He says nothing of induration; he speaks of thickening in its latter stage—a condition which may be common to many sores, and does really characterize a form of sore which he has called the *venerola indurata*, but this is not the Hunterian sore. Sir R. Carmichael is silent on the subject, as indeed is very original writer who is untrammelled by Mr. Hunter.

Observe, however, finally, that I do not contend for the error of Mr. Hunter: I contend merely for this, that the prominent character of the single form of sore which he has described is not the character of venereal sores at the present day.

This is not a question to be determined by authority. It is a simple question of fact, to be determined only by personal inquiry and observation, and to these I commend you.

OBSERVATIONS

ON

COMPLICATED SURGICAL INJURIES,

INCLUDING GUN-SHOT AND OTHER WOUNDS.

By RUTHERFORD ALCOCK, K.T.S. &c.

Late Deputy Inspector-General of Hospitals with the Auxiliary Forces of Portugal and Spain.

(As delivered in his Lectures at Sydenham College School of Medicine.)

[Continued from p. 204.]

III.—On Complicated Injuries of the Extremities.

ANOTHER kind of complication not mentioned in the last lecture, and almost peculiar to gun-shot wounds, is the lodgement of a foreign body in bones. A musket-ball, for example, is very frequently embedded in the heads or extremities of bones. Here are many very fine specimens of this kind of injury. In these may be seen musket-balls lodged in the lower extremity of the femur—in the head of the tibia, and of the humerus. There is another, with the ball embedded, as it were, in callus, between a fractured radius and ulna. Here is a portion of a ball lodged in the ilium, loose in a shell of bone produced by absorption; another very beautiful example of fracture in the middle third of the femur, with a divided portion of ball fixed between the fragments.

You have the opportunity, by examining these, of satisfying yourselves that not only must they act as a source

of inflammation by their presence, but that thus driven into the cancellated structure they split or fissure the harder shell forming the articulating surface, producing a new source of mischief. Fig. 1 affords a good example of this: the femur of a Spanish soldier, whose thigh I amputated in one of the Spanish hospitals.

FIG 1.

a, a. Lines showing the separation of the condyles from the shaft.

b, b, b. Fragments of the internal condyle.

c. The spongy portion of the condyle exposed; the table having been carried away.

d. The ball firmly lodged in the condyle.

Some doubt exists as to the best mode of dealing with these injuries. To leave the ball in is to sacrifice the limb nineteen times out of twenty, certainly when the joint implicated is the knee. To remove it will often require a troublesome and painful operation within the capsular ligament—as, for instance, to remove the ball in this preparation of a knee-joint, shewing the rapid and disastrous consequences of such an injury (see figs. 2 and 3.) This specimen presents features of very peculiar interest. In the first instance a ligamentous fibre, crossing obliquely the slit in the fibrous and capsular ligament, so closed the

FIG. 2.

This view shows the elliptical incision made by the ball, and crossed by a ligamentous fibre.

opening into the joint, as to lead to the erroneous diagnosis that the ball had not penetrated, confirmed by the patient's report that the wound was caused by a ball which fell afterwards at his feet.

At the internal side, about the centre, and an eighth of an inch to the side of the patella, may be seen an elliptical opening, showing the point of entrance of the ball through the ligamentous structure, and, obliquely traversing it, a ligamentous fibre. On throwing back the patella the ball is discovered partially buried in the substance of the bone, immediately above the articulating surface of the internal condyle. The inner surface of the patella is carious; patches only of the articulating surfaces of the femur and tibia are corroded in the same manner, except that on the surfaces of the inner condyle and corresponding portion of tibia there is not a shred remaining. The ligaments between the two bones are also partially destroyed. The ball is firmly embedded, and quite immoveable.

FIG. 3.

a, a. The femur.—*b.* Tibia.—*c.* Fibula.—*d.* Patella thrown back.—*e, e, e.* Cartilaginous structure left in patella and surface of femur.—*f.* Condyle entirely stripped of cartilage.—*g.* The ball embedded in the bone immediately above the articulating surface.

The chief features of the case may be given in a very few words. Pain and swelling of the joint set in from the first day, and were quickly accompanied by a high irritative fever, the formation of extensive abscesses, copious and fetid discharge, which ended in death on the twenty-seventh day, having in that time, as you see, produced entire disorganization of the knee-joint, the almost complete absorption of the cartilages, and caries of the bones.

The whole of the leg, from the ankle upwards, was infiltrated with unhealthy pus. An abscess of the thigh was found implicating the whole of the limb, from the knee to beyond the trochanter major, and communicating freely both anteriorly and posteriorly with the knee-joint. The femur was separated from its muscular attachment, and lay along the course of the abscess, not de-

prived of its periosteal covering, which, however, was in a putrescent state, and easily separated from the bone. The joint was filled with extremely fetid matter, of a dark grumous colour, mixed with putrescent clots of blood, which probably had been effused from some branches of the profunda, observed at the upper part of the abscess. Let this case, then, impress on your minds the vast extent of mischief which an irritating body in a joint is capable of producing in a short period.

There is, however, one method by which a limb may often be saved, though not the articulation; and that is, by removing the head of the bone. I must, however, commence by saying that I consider this totally inapplicable to the knee-joint, and an operation I should never perform. It has been done with fatal result in some, and with a very doubtful kind of success in one or two others. I have not, however, the same objection to excision of the head of the humerus, or a similar operation at the elbow. The articulation for which such an operation is peculiarly calculated is the shoulder; and gun-shot wounds, such as I am now describing—such as you see in these preparations—are those best adapted for this operation, which I shall shortly have an opportunity of demonstrating to you.

Fractures from gun-shot do not only differ from those produced by other causes—in their brittle comminution, of the distinctive marks of which you have some very perfect examples here—but in the long fissuring obliquely upwards and downwards. This almost invariably takes place, and requires that you should estimate for it in amputation, and make allowance for the injury it inflicts in your diagnosis.

One of the best specimens I have seen I now show you: it is the femur of a gallant young officer whose leg I was obliged to amputate very high up in the thigh, on account of this extraordinary fissuring. The ball passed completely through, making a hole above the cancellated texture, and splintering it upward and downward in five fissures: one you see more than six inches in length. I concluded from my examination that considerable fissuring had taken place, and made proportionate allowance in beginning my first incision. You see how closely my judgment in the matter carried me; for the saw was applied just half an inch above

the highest point of fissure, though nearly six above the passage of the ball through the bone. I amputated within five hours of the period at which he received the injury, and he recovered very rapidly.

There is still something more in these fractures than is to be observed in compound fractures from machinery, carriage wheels, falls, &c. The jar, or shock, is greater, and seems to communicate a sharper and more extensive inflammatory action on all the surrounding parts, and especially to the periosteum. Hence a more rapid and extensive suppuration. Here are eight parallel cases of gun-shot fractured femur, and fifty more of the different bones of the extremities. Examine them carefully, and you will see in all, that the action of the periosteum, of the absorbent and secreting vessels, is far extended, and rarely if ever confined to the mere site of fracture. This is not common in the fractures of civil life. And this inference is equally borne out by the notes of the cases. It is rare that a gun-shot fracture takes place in any of the bones of the extremities, without very extensive inflammatory and suppurative action—more than a mere fractured bone gives rise to in other circumstances, and out of proportion to the amount of the reparative process.

If you look again at these preparations, your first impression must be the perfect similarity of the means adopted to repair the mischief. In all there is a detaching of the sharp edges and ends by absorption of the bone behind, and the throwing out of callus in the immediate vicinity. In this one appearance, every where evident, I read a refutation of Haller and Dathleef's conclusion, after many experiments, that the callus was formed by a gelatinous juice exuding from the extremities of the broken bone. Look at these deadened and ivory extremities, evidently deprived of all vitality; see the callus every where abounding from the living bone, but no where from them, and you will feel convinced, as I do, that however callus may be secreted it assuredly is not by means of the broken extremities. I have no doubt callus is formed by aid of all the surrounding soft parts, but of the medullary membrane and periosteum chiefly, which throw out lymph from their torn and injured surfaces, into which vessels are shot for the purpose of organizing the structure, and

ultimately of secreting earthy matter—so forming, by degrees, first callus, then bone.

And in these preparations you may also read a refutation of the principle laid down, that for the formation of callus it is necessary the broken ends should be in contact. Here are two

specimens, remarkable not only for their beauty but exact similarity. Twins could present no closer resemblance of feature than these do, first in their fracture, and next in their reparative processes. In describing one observe how accurately I give the description of the other (see figs. 4 and 5.) Here,

FIG. 4.

1. Superior shaft.
2. Inferior shaft.
- 3, 4, 5. The fractured portions. The connexion by callus of the fragments 3 and 4 is seen, each forming a kind of bridge, arched in the centre and united at the ends. In this aspect the fragment 5 distinctly shews not only the dead portion about to be thrown off, but the remaining healthy bone which was secreting callus.
- a, a, a. The different points of bone nature was endeavouring to throw off.

FIG. 5.

1. Superior shaft.
2. Inferior do.
- 3, 4, 5. The fractured portions. The connexion by callus of the fragments 3 and 4 is seen, with the superior and inferior shafts, forming a kind of double bridge. In this aspect the portion of the fifth fragment seen is dead white bone, which was being thrown off.
- a, a, a, a. The different points of bone nature had endeavoured to throw off.

it may be seen, the fracture is complicated, and the reparative process not

less elaborate and perfect. The two shafts touch but at a point, and in both

the contact is with dead bone; probably in life they did not touch at all. Three large, long, and irregularly-shaped fragments are all curiously wrought together, and to each shaft, but rather in the shape of rough branches flung across a broken bridge. Every where, from shafts and fragments, sharp ends and edges are separating, and absorption strikes the line of separation. The formation of callus may next be observed immediately behind: it seems to have gone hand-in-hand with the absorbent process, and with equal activity. Thus the shafts are united, although they do not touch, connected rather by the fragments forming a bridge, firmly bound by callus to each shaft at the farther extremities: this bridge being formed by three irregular pieces of from four to six inches in length. Two of the longest flung boldly across from shaft to shaft, slightly convex and curved; the third and shorter fragment seems to have fallen in, and so at its upper extremity lies under the upper shaft, and the arch of the rude bridge. The whole of that end, however, being nearly thrown off and deprived of vitality by the absorption behind.

Could the process have gone, on it seems impossible that any solid union could have been effected, and yet quite certain that union would have been the result, exceedingly delusive and fragile in its nature, capable probably in time, of bearing the body's weight carefully placed upon it, but certain to give way under any irregular pressure, or by any fall or shock.

This one shows you the process of reparation up to the seventy-sixth day; the other parallel case gives the process up to the 136th.

It is necessary now to compare the two. It seems very evident, from the consideration of these preparations, that the first efforts of the system are vigorous and rapid in proportion; for in the first (which I have described,) during fifty-three days already are all the points of bone distinctly circumvallated and partially detached. Already are the shafts and fragments arranged in such order as to allow of consolidation more or less perfect. In the second, what has been done in eighty-three days more? A greater quantity of callus has been thrown out, and the edges and points in some instances are entirely detached, in others

nearly so; but observing the work of fifty-three days, and then turning to the effect produced by eighty-three additional, it becomes evident how much more slowly the united actions of absorption and consolidation have proceeded. There is some little difference also to be observed in the character as well as the quantity of callus in the latter, showing the longest period; it is more rounded, partaking more of the peculiar and porous character of lava, which it much resembles.

Having called your attention pointedly to the abundant formation of callus uniting fragments to the shaft in contact but at a point, and thus indeed, not only uniting themselves to the shafts, but connecting the two, let me beg you to observe again this fissured and broken femur, which I have already shown you; there is a square piece attached now by gum; you see at once that it has been completely detached, that it is whiter than the rest, or in other words, that its vitality is gone; yet within five hours from the shot striking the bone I amputated the limb.

These two facts are placed in juxtaposition, the better to enforce two points of practice:—

First, since fragments, particularly long and irregular ones, generally in contact at one or more points, will not only unite in a firm and perfect manner, but serve as a useful connecting link to the shafts, since moreover, such fragments have extensive adhesions to muscular fibres, and if lying deep can only be extracted with much dissection and some violence, this operation, under such circumstances, ought never to be attempted.

Secondly, that a completely detached and short fragment should be removed at once if it can be done without much dissection or violence, as it is likely, in a few hours, to become dead, and lie in the wound a foreign body.

Other conclusions I have also come to, on a careful consideration of these preparations, and the cases which produced them, viz.

That there is a relative and proportionate activity of the absorbent and secreting vessels in fractured bones.

That the different functions and actions brought into play by the fracture, and which must chiefly act through the periosteum, display a constant ten-

dency to extend far beyond the seat of injury.

That the activity of the reparative process is greatest at first.

That time gives no correct criterion of the degree of reparation effected.

That any modified or morbid action of the periosteum exercises the most important influence on the issue of a case of fracture.

Lastly, that the process adopted by nature in gun-shot fractures, of the femur especially, is protracted and exhausting, bearing no proportion to that resulting from similar fractures of other bones.

Hence a principle of practice to bleed but very sparingly during the inflammatory stages, and not at all unless it is very urgently indicated; remembering the long exhausting process which must follow, and that on the strength and resources of the patient's constitution will depend, in a great measure, the successful issue of the case.

With these conclusions, having already gone at some length into the facts on which they are founded, I can very shortly give the practice which results.

From the numerous cases I have seen myself, added to all on the records of military surgery, under no ordinary circumstances can I consider it justifiable to reserve a gun-shot and comminuted fracture of the femur—and comminuted they almost invariably are—for treatment with a view to save it. Out of thirteen cases which, from unavoidable circumstances, were thus the subject of treatment after an action, but one survived without secondary amputation; and he, at the end of two years, was bed-ridden with a useless limb; and in twenty others, one of three results were observed: they either died without the opportunity for operation; or, 2dly, amputation became obviously the only resource; or, 3dly, they survived bed-ridden with a useless limb: and these were all young and healthy men.

In gun-shot fractures of the leg and foot, very extensive comminution of bone, and severe laceration of soft parts, may make amputation even here advisable as a first measure. The majority, however, if not otherwise complicated, may be saved. Even a grape-shot will sometimes obliquely traverse the leg, causing, of course, very extensive laceration, and yet the patient do

well. Two such cases came under my notice.

Gun-shot fractures of the humerus, if much comminuted, or pulverized as I have seen them, offer but small chances of recovery. One of the worst cases I have noticed occurred with M. St. Leger, the Comde de Bemposta, and aide-de-camp of the late Emperor Don Pedro. On the 29th of September, 1832, his arm was severely shattered about the centre by a musket-shot. By great care, with every means and appliance, many counter-openings for matter and extraction of fracture, he ultimately recovered, after many months of suffering. When I last saw him, some five years ago, not only were all his wounds healed, but he could give a moderately cordial grasp with the hand of the injured arm—quite cordial enough for a courtier, at all events.

These cases are very tedious, and give rise to extensive mischief in the surrounding soft parts. Yet still, except in extreme cases or where there is very close proximity to the joints, the attempt may always be made with propriety to save them.

In the forearm there is scarcely any degree of injury to bone from a musket-shot that can require or justify amputation in the first instance. Shortly after the landing of the army in Portugal, while the English were still *pêle-mêle* with the Portuguese, in their hospitals, I was searching out the English wounded, that I might have then separated and classed, in order to attend to them myself, when the Director pointed out one to me, saying that he and his colleagues purposed, if I had not come, to have amputated the arm. On examination, I found it was a comminuted gun-shot fracture of both radius and ulna in two places, and, thanks to the bandaging he had undergone, the arm was swelled, tense, and ill-conditioned in its appearance. I begged that he might be left to me, stating that those were cases which English surgeons always endeavoured to save, and generally succeeded. At this moment, Don Pedro, with his staff, paying a visit to the hospitals after the action, entered the ward, and coming up to me, seeing an ugly-looking arm in my hands, said, in his usual sharp and abrupt manner, in French, "I hope you are not going to cut it off!" I replied that I was not. "Ah!—bien,

bien!—Glad of it, for I know you English think nothing of lopping off a limb!" I thought this somewhat hard, since I had just snatched it from the knife of his own people, and told him I was much prouder of saving a limb than cutting one off: and then he told me an anecdote of some English colonel who had said, after losing a leg, that he was sorry he had not lost an eye also, as the double pension would just have made him comfortable. He evidently entertained an impression, that not only had we no just value for eyes and limbs, but an exceeding covetousness for the pensions, which would have to come out of his exchequer. However little accustomed, probably, to hear an opposite opinion urged to his own, he always remembered it, and rarely passed me, either in Oporto or Lisbon, afterwards, without stopping and asking me half a dozen rapid questions. Notwithstanding his Imperial Majesty's opinion of English surgeons, I saved the limb, and made it a useful one too; and this will generally be found possible.

Here is an example of failure, however: you see the ball imbedded and crusted over with callus, lying between the radius and ulna. This wound, after many weeks' treatment, produced a permanent twisting downwards and contraction inwards of the hand, so as to render it not only useless but exceedingly inconvenient; and all measures failing to prevent or amend it, the arm was amputated. But had the ball been discovered and extracted in the first instance, I have little doubt that a useful hand might have been saved*.

A CASE OF COMPOUND FRACTURE OF THE ULNA.

Mortification—Amputation—Recovery—Appearance of the Limb on Dissection.

WITH REMARKS.

To the Editor of the Medical Gazette.

SIR,

SHOULD you consider the following case of sufficient interest for insertion in

* ERRATA IN LAST PAPER.—The paragraph immediately succeeding fig. 4 referred to a sketch not used. The note at the end, purporting to describe the woodcuts, was also inserted by mistake, not referring to those engraved.

your valuable periodical, it is much at your service.—I am, sir,

Your obedient servant,

WM. ROBBS, M.R.C.S.

South Terrace, Grantham,
April 10, 1839.

B. Henson, aged 27 years, a stout-made man, who is occasionally subject to epilepsy; while repairing a chimney, on the 15th of October, 1838, he was taken in a fit, and fell from the top of the house, a distance of about forty feet. The fall was broken by his right arm catching on the iron palisade, and becoming partially transfixed. It fractured the ulna, about midway between the elbow and wrist-joints, into several portions; a great destruction to the skin, cellular membrane, and muscles, also took place. He was unable to stand; the left side and thigh were much contused. At this time (9 o'clock A.M.) the skin is cold; the pulse feeble, and scarcely to be felt; and he appears unconscious of what has happened. I placed the injured parts in position as far as they could be, and retained them there by means of sutures and adhesive plaster. After the wound was dressed and splints applied, so as to keep the arm between supination and pronation, he was placed in bed.

2 o'clock P.M.—Great pain is experienced in the injured arm, and slight bleeding has taken place, but to no great amount. The surface of the body is warmer, with a pulse of 96, and very feeble. The lower part of the arm and hand are growing warmer, but re-action is not yet re-established.

Sumat. Mist. Magn. c. M. Sulph. f.ʒj.
4ta quaque horâ.

7 o'clock P.M.—He has had an epileptic fit, during which he struggled a great deal. There has been slight bleeding from the arm; the pulse is 100, and full; the skin warm; the countenance flushed; and he complains of severe pain in the injured arm, left side, and thigh.

Fiat Venæsectio ad lb.j. Repet.
Haust. omn. horâ donec alvus responderit.

16th, 10 o'clock A.M.—Has been very restless during the night; the bowels have been evacuated; the upper part of the arm is very hot, while the lower part and hand are cool, and of a dark colour. The pulse is 110, and soft; and he complains of pain in the arm and

about the elbow. On removing the bandage, the sore presents a very unhealthy appearance.

- Ordered a poultice of ale-grounds and linseed-meal to be applied every four hours. Sumat T. Opii, ℥xl. statim. P.

I was absent from home from this time till 10 o'clock A.M. the following morning, during which, he was under the superintendence of my friend, Mr. Higham. In the evening, violent symptoms of pyrexia came on; the pulse was 140, full, and hard; the face was flushed; he was extremely delirious, and very restless.

Anodyne and saline remedies were given.

17th, 10 o'clock A.M.—He has been extremely restless during the night; the face is highly flushed; the pulse 140, soft, and intermittent; the lower part of the limb is quite cold and senseless. There is a very feeble indistinct pulsation to be felt over the radial artery, but not the least over the ulna; and on pricking and pinching the fingers, no pain or sensation is communicated. The inflammation has extended between two and three inches above the elbow; the wound is very offensive, and in a state of sphacelus. The surface of the skin is of a dark colour, quite purple over the hand and fingers; the cuticle is raised, and the cellular membrane appears light and spongy, discharging large quantities of ichorous matter as if from fermentation.

I met Dr. Turner and Mr. Higham in consultation, when it was agreed the limb should be removed by amputation without further delay. At half after eleven o'clock, in the presence of Messrs. Higham and Jeans, I commenced the operation by the circular incision; the limb was removed in a few minutes, with the loss of only two or three ounces of blood. He bore the operation well, never once complaining of pain, which I conceived to be an unfavourable symptom. The limb was separated about two inches below the shoulder joint, and, after taking up the arteria humeri et arteria circumflexa superior, the stump was dressed in the usual way, bringing the edges of the flap together by means of strips of adhesive plaster; and he was subsequently placed in bed.

Sumat T. Opii, ℥ xl. c. Aquæ Cinnam. f. ʒi. statim. Diet, beef-tea, Port-

wine, with sago or arrow-root alternately, every two hours.

18th, 9½ o'clock A.M.—Has passed a comfortable night; has had no pain; the stump feels warm, and the skin is moist, and of natural temperature. The pulse is 120, weak, and irritable; the tongue moist, and rather white; the countenance natural. He is perfectly sensible, and says he feels much relieved from the operation.

B. Morphiæ Hydrochloratis, gr. j. Confect. Aromat. q. s. Fiat pil. iij. quarum j. sextâ quâque horâ sumenda.

Vespere.—Continues much the same, but has had slight spasmodic twitchings during the day.

Sumat T. Opii, ℥ xl. e. Hydr. Chloridi, gr. iij. horâ somni. Haust. Olei Ricini, f. ʒi. cras mane sumendus.

19th—Has had a good night, and appears in every respect going on well. The bowels have been relieved; the discharge from the stump is rather profuse, serous, and very unpleasant. From this time he continued to go on much in the same way till the sixth day after the operation, when the stump was dressed.

On removing the strips of adhesive plaster, the upper part of the wound is closed by adhesion, but considerable discharge of pus mixed with sanious matter is voided from the lower half, and at this part little or no adhesion has been effected; and a slough, the size of a crown-piece, is visible on the upper edge of the wound. The skin is warm and moist; the tongue clean; the pulse 100, stronger, and more natural. The stump is perfectly sensible, and he complains of pain in the fingers and hand of the removed limb.

Diet—mutton chop and pint of ale daily, in addition to his beef-tea, port-wine, sago, &c.

Eighth day after the operation.—The plasters are again changed; the discharge from the lower part of the wound continues, but it is of a more healthy appearance, and not so much in quantity. Pergat.

Tenth day after the operation.—The slough on the upper and outer part of the wound separated, and came away within the plasters; and the granulations appear healthy. In all respects he is doing well.

On the thirteenth and sixteenth days after the operation the plasters were

changed, when but slight improvement, as far as the healing process was concerned, had been effected. The axillary glands were enlarged, and the skin of a red colour. The constitutional symptoms keep improving.

Oct. 31st.—On changing the plasters the ligature came away with an extensive slough of cellular membrane, followed by a slight discharge of blood. A moderate rate of pressure was made in the axilla, and continued downwards by means of a pledget of lint and adhesive plaster.

Nov. 5th.—The discharge from the wound has been slight since last report, and on removing the plaster it is nearly healed.

8th.—This evening, while he was walking across his bedroom, he suddenly fell down in a fit, during which he struggled violently, and struck his stump against the floor and a box that stood near, which caused the loss of about three or four ounces of arterial blood. His sister states it to have "come out of the wound in a jet, as if from a pump." On my arrival the hæmorrhage has ceased, but the stump is much swollen and extremely sensitive, so much so that he will not allow any one to touch it. He was ordered to be placed in bed, and to have linen rags wetted in an acetous lotion constantly applied to the wound and upper part of the shoulder.

R Pulv. Opii gr. $\frac{1}{2}$; Hydr. Chloridi gr. j. ex pil sexâ quâque horâ cum haustu sequente.

R Mist. Mag. c. Mag. Sulph. f. $\frac{3}{4}$ ij. ex hausta. Diet—milk and sago, or arrow-root.

9th.—No return of the hæmorrhage; the stump is much swollen round the edges of the wound, and its lips are open and very tender. The bowels have been freely acted on, and towards this morning he got some sleep. From this time he was kept to his bed, the stump healed slowly, and with great contraction of the integuments. An abscess formed in the axilla, which communicated with the wound by a fistulous sinus; but by keeping up a gentle pressure by means of pledgets of lint and adhesive plaster, the communication with the latter was cut off, when the former readily healed.

Owing to this man being subject to epileptic fits, during which he would fall down and struggle violently, I had

a boot made for the stump and stuffed with cotton, which proved a great protection to it.

Appearance of the limb on dissection.—The skin was highly discoloured, and the cutis was easily to be stripped off. The cellular membrane was highly injected with serum, which caused the limb to be much swollen as high as the elbow-joint; but the redness and inflammation had extended for three inches above this part. The fascia was lax, and much gorged with fluid; the muscles on the outer side of the arm were in a natural state, except that they might be more relaxed than usual. All the flexor muscles were of a very dark colour, and about the injured part no attempts at separation had taken place. The arteria radialis was normal, but the arteria ulnaris for about two and a half inches opposite the wound was of a black colour, and had evidently lost all vitality; the anterior and posterior interosseous branches were in a similar state. The veins were filled with a thick dark-coloured blood; and their coats, in the neighbourhood of the wound, were of a pink colour. The absorbent vessels about the elbow-joint had the same appearance. The ulna was fractured obliquely, and the fracture comminuted.

REMARKS.—In the foregoing case a question arose whether amputation ought not to have been resorted to on the receipt of the injury; but when the circumstances of the patient were taken into consideration, that he was entirely dependent on his manual labour for his subsistence, it will be evident that it was most desirable to preserve the limb if possible, and his age and constitution were favourable for that purpose; in fact, his limb was of as much importance to him as his life. The wound putting on the appearance of sphacelus, and the inflammation having advanced above the elbow-joint, left no other alternative but immediate amputation to save the patient's life. A portion of the stump subsequently assuming the same appearance as the wound, indicated an unfavourable result; but by a generous diet, and a liberal allowance of port-wine, enabled the constitution of the patient to recover itself. The sudden loss of blood caused by the accident, which happened on the 8th November, must have been discharged from a small

branch, and not from the principal artery, otherwise troublesome hæmorrhage would have ensued. The subsequent contraction of the skin, together with the loss of substance caused by the slough, exposed a small portion of the bone, which exfoliated; and subsequently the wound healed perfectly sound and healthy.

EFFECT OF WARM FLUIDS.

To the Editor of the Medical Gazette.

SIR,

A RECENT observation of a series of morbid phenomena, often noticed before, but not till now sent beyond the limits of my common-place book, has induced me to solicit admission for them into your widely-circulating journal; having the honour to remain, sir,

Your obedient servant,
NATHANIEL RUMSEY.

Beaconsfield, March 29. 1839.

Symptoms of Irritation—Pseudo-fever—Effects of warm Fluids received into the Stomach.

I have not unfrequently been struck with the good sense of a popular author on education, who, somewhere in her writings, draws an analogy between facts worthy of preservation, though not intelligible, and articles to be laid by for a future day, when circumstances may arise calling for their use. During my opportunities of observing disease I have been in the habit, when meeting with phenomena which I could not understand, nevertheless of noting them down, and looking with some hope for light on the subject to future experience, frequently appending to the memorandum an interrogation, such as, "What is the explanation of this?" "What is it?" &c. I have very often had the satisfaction, at the distance of eight, ten, or more years, of adding the reply, the solution being derived from a further accumulation of facts. I have also borne in memory many similar interrogations, without particularly noting them down; and to these also, after a lapse of years, have been able to furnish a reply. It was so with regard to a set of phenomena long ago noticed, and since receiving an explanation

which I think of sufficient importance to preserve with care. I have never heard that any similar view of them has been taken, and not doubting that they must often have led practitioners into serious error, I feel called upon to submit them to the medical reader.

My first view of these phenomena is recorded in the following narrative:—

Many years ago I was myself the subject of typhus fever. Having passed through the disease, my debility was great, and convalescence interrupted by what appeared to be the daily occurrence of symptomatic fever; the cause not obvious, but suspected to be a pulmonary affection. After a great length of time, an unfavourable prognosis, and groundless anxiety in my friends, I recovered. The regular depression of bodily and mental power, which began about eleven o'clock A.M. daily, the heat of skin, quick pulse, and sweating, gradually left me. No confirmation was, by the termination, added to the opinion that local disease had existed; and the correct understanding of the case—to use the principle of the writer on education—was reserved for a future day. It became apparent to me at the distance of many years afterwards, made so by other facts, that these symptoms had been the effect of drinking daily for breakfast a large basin of warm milk, under the state of debility induced by the long-continued disease. I do not doubt that many similar facts may have occurred to me within the next few years, and as little understood; but in my subsequent experience, I have been brought to a confident belief that they are of no unfrequent occurrence, and that their cause is as clearly made out as it is important to be known.

These phenomena, which are, as it were, a mimicry of irritative fever, or that which is symptomatic of local disease, are particularly incident to patients reduced by loss of blood. I will therefore recite another case of recent occurrence, in a patient under that condition, to elucidate my meaning, and exhibit the importance of a correct view respecting it.

A lady having miscarried in the middle of the fourth month, suffered under repeated and alarming attacks of uterine hæmorrhage for three weeks; in consequence, as it was supposed, and afterwards proved, of a retained pla-

centa. I assisted in removing it at the end of that time, with much difficulty, and in separate portions, fearing much the consequences which might follow the unavoidable employment of the means used for this indispensable alternative. No symptoms but those of an exsanguined and weakened patient followed through the critical period of the next four days, after which, to the concern of my son, Mr. John Rumsey, who was in attendance, some circumstances arose which rendered him dissatisfied with the symptoms and progress of the patient. He reported that she had had, on several successive days, a paroxysm, marked by heat of skin, profuse sweating, great depression of all the powers of body and mind, a tongue thickly furred, slimy and dark in the centre, a pulse very feeble, with an increase of forty beats in a minute, and great dependency on her own part as to recovery. Hence, he expressed his fear that some source of irritation was still in existence (at that time a very probable thing), and augured unfavourably of the issue. Seeing her now, after some days' absence, a little inquiry led me to believe that this apparent fever was mere irritation, arising, as in the various other cases which I had seen, solely from receiving into the stomach a bulky, warm, and vapid fluid; and I was confirmed in this opinion by being able to trace, with the assistance of the patient, that the symptoms had, on one occasion, followed the use of two or three cups of tea, and at other times the liberal potation of warm chicken-broth. I was thus able, with great confidence and pleasure, to give a favourable prognosis.

I directed that evening that she should take a draught of good home-brewed ale, cold from the cask (Jan. 1 or 2), thus combining the exhibition of nourishment and a stimulus to the system, with the application of cold to the stomach*.

The purpose was answered equal to my expectation. Animal food in small

quantities and malt liquor, were continued, and a careful disuse of the warm fluids observed. It is now several weeks* since this change was made; no paroxysm has returned, and nothing has interrupted a daily improvement, the case having exhibited another instance of the peculiar affection I wish to describe.

I have seen this disturbance of the system usually assume the form of a paroxysm of fever, but on some occasions to consist of successive fits of fainting and hysteria; nevertheless coming on as a fit of fever, in point of time and duration†.

If I might venture a conjecture as to the *modus operandi* of the warm fluids, I would suggest that the heart, morbidly sensible, responds too promptly to the stimulus of heat, when introduced into its neighbouring organ—the stomach, in so bulky a form as in the cases quoted and referred to; but in its endeavours to obey, incommenced by the pressure of bulk, and incompetent to a normal action by debility, makes its embarrassed struggles, disturbing the whole system by the failure and perversion of its function.

Nothing can be more simple than the indication of cure. Nourishment without bulk, stimulus regulated as to degree by judgment and discretion, not only without warmth, but actually cold internally; with rest, tonics, and attention to warmth externally.

The importance of distinguishing the true character of these symptoms is not as the danger which they threaten, but as the danger which may be connected with an erroneous view; leading to a wrong prognosis, and the institution of remedies upon a wrong principle.

The previous debility or nervous temperament of the patient, the absence of satisfactory evidence of local disease, the effects of the concurrent use of warm fluids, and the febrile symptoms, often marked by unusual depression of spirits, may justly excite suspicion of the cause, and lead to a correct diagnosis; whilst nothing has served so

* Of the power of cold applied to the stomach, to allay a very disturbed and distressing action of the heart, I frequently saw an instance in the late well-known old huntsman of the Berkeley Hunt, who, after the failure of æther and other stimuli, found an admirable remedy in swallowing a bottle of cold soda-water, which always instantly relieved him. I also have frequently seen a cold fluid swallowed act as an auxiliary in lowering arterial action in various febrile conditions.

* Three months have now elapsed, and the patient's restoration is nearly completed.

† A lady, on whom a slight operation had been performed in the face, having had previously no fever, became agitated and hysterical. She had, the next day, a strongly-marked paroxysm of fever; no doubt arising out of the previous day's hysteria. It never returned.

powerfully to establish the view which I have taken as the subsidence of the symptoms upon the use of the cold tonic principle. The frequency of this condition has been such, that I fully believe its occurrence to the notice of any attentive observer having moderate opportunities, could not be rare.

There is a febrile condition more immediately incident to loss of blood, which, so far as relates to its intimate connexion with debility, bears some analogy with this state. I first observed it about the 1817, and having shortly afterwards seen it again several times, and under various circumstances, communicated an account of it through the *Edinburgh Medical and Surgical Journal* for January 1819 (vol. xv. p. 55), with my opinion of its importance. I do not know that any account of such a state had been published before; but I had the pleasure to see, some four or five years afterwards, that a similar observation and opinion had been made and published in the writings of two distinguished pathologists of the present day, whose high character had so stamped an important value upon it, as to have obtained for it a place in the catalogue of important modern medical improvements*.

DIAGNOSIS IN ADHERENT PERICARDIUM.

To the Editor of the Medical Gazette.

SIR,

As the opportunities of obtaining post-mortem examinations are comparatively rare in illustrating the pathological condition in cases of rheumatic pericardites, I am induced to offer from my "Note-Book" the following case, which, should it prove worthy a place in your journal, you will greatly oblige,

Your obedient servant,

PERRY DICKEN, M.R.C.S.

Ashby-de-la-Zouch,
April 1839.

Amelia Harris, æt. 18, a girl originally of stout frame and healthy constitution, was admitted into St. George's Hospital, Dec. 22d, in a very emaciated and debilitated state, and giving the

following history of her case; states, "that about six months before her admission she was laid up with a severe cold, which was followed by some feverish excitement, and subsequently she was attacked with acute rheumatism, affecting the arms, wrists, and hands; she was placed under medical treatment (and as the inflammatory symptoms became aggravated), and was bled extensively, both generally and locally. Under this active treatment the pains in the limbs gradually subsided, but soon after she began to experience much uneasiness from inordinate action of heart, which continued to increase, up to the time of her admission." On coming to the hospital, Dec. 22d, present symptoms are great debility and much irritability of the system; countenance pale, sunk, and anxious; breathing short and frequent; pulse 80, full, jerking, and very intermittent; skin hot and dry; lips perfectly livid, from apparent loss of blood; inordinate and tumultuous action of heart, which is felt beating over a very large surface, and sensibly elevating the ribs; much tenderness in epigastric region on pressure, and over the cardiac region also.

Stethoscopic signs.—Distinct rough friction sound (the to-and-fro sound of Dr. Watson) accompanying the alternate motions of the heart, so loud as completely to obscure the natural sounds of the organ, heard distinctly over the entire left side of thorax, and under both clavicles, and conveying the idea of a very rough grating noise to the ear; great dullness on percussion over the whole cardiac region to a considerable extent.

Hirudines x. regioni cordis statim.

℞ Hydrarg. Chlorid. gr. iij.; Pulv. Opii, gr. ss. et rept. 4tā quaque horā. Ol. Ricini mane. Emplast. Lyttæ regioni cordis post hirudines.

25th.—No alteration in the symptoms; pulse 120, sharp, small, but has become quite regular; expresses herself a little better; some sickness and irritability of the stomach; friction sound very distinct, and there is a sense of roughness communicated to the hand when applied over the region of heart; dullness on percussion still very extended.

Pt. in usu Hydrarg. Chlorid. ut antea.

℞ Acid. Hydrocyan. Dilut. ℥iv.; Misturæ Camphoræ ʒj. ter die.

* *Cyclopædia of Medicine*.—"History of Medicine," p. cix.

29th.—Gums slightly touched by the mercury; complains much of pain in left shoulder and arm, of a rheumatic character, and also of some tenderness in left mamma.

Hirudines viij. parte dolenti pectoris.

Jan 1st.—Considerable inflammation of the integuments over the left mamma, of an erysipelatous character; is occasionally delirious, and talks incoherently. Pulse very rapid, but quite regular; friction sound very loud and very rough in character.

Pt. in usu Hyd. Chlorid. ut antea, 8vā. quāque horā.

4th.—Countenance very anxious; has some cough, and much disposition to vomiting; considerable pain in chest, and breathing very short and frequent.

Pt. in usu remed. ut antea.

12th.—Heart somewhat quieter, and the action not extended over so large a surface; grating sound less distinct, and the valvular sounds can be heard over the region of heart; much irritability of stomach, and erysipelatous inflammation still spreading.

Omitt. Pil. c. Hydrarg. Chlorid. et capiat Haust. Salinum c. Tr. Hyoscyam. ℥ xv. 6tis hōris.

17th.—Heart's action very much lessened; impulse not so great; countenance less anxious; pulse quieter.

Auscultation.—Friction sound very much lessened, and the double beat of heart is distinctly heard; a slight bruit accompanying the first or ventricular contraction.

Pt. in usu haust. Salin. Effervesc.

18th.—The erysipelatous inflammation has spread itself over the whole thorax; she appears very low; pulse quick and small.

Auscultation.—Friction sound entirely gone; a bruit still exists, accompanying the ventricular contraction.

Vin. Rubri, ʒij.; beef-tea, &c.

Died next morning.

Post-mortem examination 36 hours after death.—Body not much emaciated. On opening the thorax, the left lung was found adherent, and an immense deposit of lymph and pus was found on the surface, completely coating it; no adhesions on the right side.

Heart of its natural size. The cavity of pericardium entirely obliterated, the opposed serous surfaces of the membrane

being completely glued together by recent but firm adhesions both on the anterior and posterior part; there was a considerable deposit of organized lymph, giving it a shaggy appearance; the adhesions were easily broken down by a little force. Some vegetations on the aortic valves, otherwise healthy; heart very flabby.

REMARKS.—From the history of the foregoing case, I am induced to offer some remarks, there being many points worthy of observation, which I shall arrange under three heads, viz.—

1st. The state of the patient on her admission, and the previous measures which had been adopted in the treatment of the disease.

2dly. The liability to metastasis which occurs in acute rheumatism, and its tendency to attack the fibrous membrane of pericardium.

3dly. The complete and correct diagnosis which was formed of the disease by stethoscopic examination.

1st. The state of the patient on her admission, &c.

It would appear from the history of the case, and from the bleached appearance of the patient, that blood-letting had been carried to a very considerable extent previously to her admission, with a view of relieving the inflammatory symptoms; and these measures, which at first appear to have materially lessened her sufferings, and relieved the acute pains in the joints and limbs, yet from the debility induced, the constitution was left in so irritable a state, that a predisposing cause existing, metastasis to some other organ readily occurred, and the fibrous membrane of the pericardium became at once the seat of the inflammation. Whether we may be disposed to view this metastasis rather as the result of the activity of the disease itself, or to the exhaustion produced by the depletory measures adopted in the commencement, will of course be a subject of speculation; but I am inclined to think, from the great quantities of blood which had been drawn, that much of the mischief arose from the latter cause.

2dly. The liability to metastasis occurring in acute rheumatism, and its tendency to attack fibrous membrane of pericardium, &c.

This fact until later years had much escaped the observation of pathologists,

but has now been so completely demonstrated, that all doubts on this subject seem to have been laid aside. M. Bouillaud, indeed, goes so far (I believe) as to advance that there are very few cases of acute rheumatism in which the fibrous membrane of the pericardium is not implicated. I am much inclined to think that it does very often occur; but often so slight as not to be detected unless particular attention is directed to the organ. I do not, however, conceive that M. Bouillaud ever regards blood-letting at all as an exciting cause of the disease, for his practice is diametrically opposed to such an opinion, consisting in the free and repeated abstraction of blood until the inflammatory symptoms are subdued, and the circulation quieted; but his attention at the first onset, and during the progress of the disease, is carefully directed to the heart, in order that he may be enabled to ascertain the first symptoms, and attack the disease *in limine*.

3dly. The correct diagnosis afforded by stethoscopic examination.

This happened to be a case in which the auscultatory signs were so remarkably clear, that no possible doubt could exist as to their certainty. On the patient's admission, when the lymph had been recently thrown out, the "to-and-fro sound" was so distinct that it could be at once appreciable to any one, however unskilled in the art of auscultation. All the natural sounds of the heart seemed quite drowned in the morbid development; subsequently the gradual decrease in the intensity of the sound marked that adhesion was commencing; and finally, its total decline before the death of the patient, proved beyond a doubt that adhesion of the serous surfaces must have taken place, and therefore it became physically impossible that the friction sound could any longer exist.

In offering these remarks I have nothing new to bring forward, I merely wish to communicate facts; and as it is these which we chiefly are in want of in investigating disease, I was induced to offer my mite (however insignificant it may appear); should it, however, have the effect of altering the opinion of any one member of the profession who is credulous on the subject of the signs to be gained by auscultation in this disease, my object will be fully answered.

Artis Medicæ tueri; potestas modo ventendi in
publicum sit, dicendi periculum non recuso."

CICERO.

MEDICAL CHARITIES.

HUMAN nature, said Luther, is like a drunken trooper on horseback; down he falls on one side, and if you set him up, down he falls on the other. This piquant saying of the great reformer is curiously exemplified at this moment, in the relief of the poor. Some half dozen years ago the error was supposed to be on the side of indulgence. "You are turning all the poor," cried the Malthusians, "into spoiled children; the workhouses have become so many well-furnished taverns; beer and pudding are to be found in these epicurean asylums; and, instead of teaching ploughmen how to read Bacon (as Lord Brougham wished), you are teaching them how to eat it."

These outcries had their effect; beer and bacon have disappeared; and the workhouses, changed by the harlequin touch of an act of parliament into Union Bastilles, have become spots for trying experiments on human beings, and ascertaining the minimum of water-gruel just above the dysenteric point.

This is a splendid victory; but your true starver,

"Nil actum, reputans, si quid superesset
agendum,"

is far from being satisfied. He considers this a mere ovation, when he had hoped for a triumph. He longs to pursue misery into all its fastnesses; to haggle with it; to reproach it with all its transgressions; and lastly, to give it —his advice. With the present distribution of the poor-rate our political economist is pretty well contented; but are there not other sources of relief, which, as he says, tear up every social bond by the

roots, and are rapidly turning England into a wilderness? Are there not almshouses, where luxuries are lavished on the thrifless? Do not many make it their business to corrupt society at the very core by giving meat, coals, and blankets, to persons found guilty—on the clearest evidence—of being penniless? And last, not least, are there not hospitals where disease is admitted without inquiring how many children the patient has? and where reckless physicians take in the starving, and call the malady *atrophia*?

This last branch of Malthusian complaint has been dilated upon by one of the physicians of Sheffield, in a volume now before us*, which will be nuts to the economists. The late Mr. Walker, the police magistrate, in his work, called *The Original*, hinted pretty broadly that he wished to put a stop to all charity, public and private; but with this exception it would be difficult to find any one so retentive as the author of the "Inquiry." His charity is infinitesimal; and instead of falling, like the dew of heaven, on all who may require its influence, comes like an ungracious spirit on the heads of a select few. To find patients for an infirmary is generally an easy task; but so near an impossibility, if the author's tests are adopted, that we would rather beat up for recruits for the most select and exclusive regiment in the service. Become of his sect, and you may pull down three-fourths of the hospitals in London to-morrow, or convert them into lodging-houses for assistant commissioners. When the drummer, in the story, was flogging a deserter, the unfortunate man cried out, "too high! Too high!" and when the drummer endeavoured to

comply with what seemed to be his wish, he exclaimed, "Too low! too low!" Now this is the author's case to a T; his patients are either too high or too low. If they come in silk gowns, with nice shawls and clogs, they are too rich, and should be sent to their own doctor; if they are shirtless and shoeless, hungry and forlorn, they are too poor, and should be sent to the workhouse. The Irish, it seems, are often convicted of extreme indigence, and, as a general rule, would be rejected by this test.

But, perhaps, the reader may say, "it should go hard with me but I would slip into the Sheffield Infirmary; I would gratify this stern exclusionist by the decent mediocrity of my dress: a thread-bare coat, a checked shirt, and patched shoes, would find the road to his heart, and I shall be taken in." Never was there such a mistake. For

"1. Single men in employment have not the slightest claim.

"2. The married operative in work, with no family, or only a small one, is equally unentitled.

"3. The operative receiving high wages, though he may have several children, cannot be regarded as necessitous.

"4. The operative who has sons or apprentices working for him, can establish no claim to relief.

"5. Neither male nor female servants in place, and attending to their respective duties, nor apprentices whose masters are in good circumstances, are proper objects."

In Beaumarchais' exquisite comedy, Figaro says that you may print what you please at Madrid, provided you speak neither of religion, nor politics, nor the court, nor the law, nor the theatres, nor any one who has any thing—under the inspection of two or three censors. So at Sheffield, under the improved system, you will get into the infirmary if you are neither rich, nor poor, nor single, nor married, have neither a small family, nor a large one, nor a ser-

* An Inquiry into the moral, social, and intellectual condition of the industrious classes of Sheffield. Part I. The abuses and evils of charity, especially of medical charitable institutions.

vant, nor an apprentice — subject always to the approbation of the physician of the day. On the 28th of January, in this year, seven patients applied to the author for admission; four were rejected, “presenting no clearly defined maladies, or such as required particular attention.” The fifth was inadmissible, being a fever case. The other two were admitted, one undeservedly so, but the author tells us that he was tired of rejecting. The seventh, as we are left to conjecture, belonged to one of the few and thinly-peopled classes that not only are, but ought to be, admitted into the most exclusive of all infirmaries.

Again, in order to contrast the present ruinous system with absolute perfection, the author takes a hundred in-patients indiscriminately, and, dividing them into twelve classes, shews who ought and who ought not to have been admitted. The first division consists of seven widows, two single women in no permanent situation, and three persons with five or six children each; making just a dozen out of the hundred. Two other classes given in the list are not mentioned in the commentary. They are, two persons having seven or eight children each, and two widowers. According to our author’s rules, a man is to be rejected if he has children old enough to work, which might probably be the case with the “two persons;” but there is no law touching widowers. Hence we can only be sure of the genuine admissibility of 1 in $8\frac{1}{2}$ of those actually admitted; and 88 times in 100 the money of the subscribers was wasted in a manner which our brother of Sheffield deplores throughout his hundred and thirty-two royal octavo pages.

This is good Malthusian jargon, no doubt; but did the founders of hospitals think after this fashion? Did the lovers of the human race, to whom Eu-

rope is indebted for its charitable institutions, apply these critical tests, and endeavour to prove to poverty that she was in the wrong?

Let a French writer answer the question:—Christian charity, he says, “dans son immense amour pour les hommes, ne fait aucune exception de leurs maux, et voudrait les soulager tous. Son zèle ardent ne connaît point de bornes à ses secours: ce qui est misère, elle l’assiste; ce qui est nu, elle le couvre; ce qui est faiblesse, elle l’excuse; ce qui est crime, elle le pardonne*.”

This is the height of benevolence, a height which some may find it difficult to attain; but what shall we say of the modern proposals to go below zero on the scale—to cut off the supplies destined for the relief of the sick—and, under pretence of teaching frugality and foresight, to leave misery without succour?

The fact is, that the founders of those great asylums for disease which do honour to humanity, had seen the manifold suffering to which the sick poor were exposed; sometimes perishing for want of assistance; sometimes injured by the attempted aid of the unskilful; and sometimes overwhelmed with debts incurred for medical advice. They saw and acted. Not a trace of the restrictions proposed by the Sheffield physician is to be found in the regulations of their hospitals. Neither servant, nor apprentice, nor single person, is excluded. No married man is to be rejected because he has so few children that he may maintain them, or so many that they may maintain him.

As for the Sheffield Infirmary being constantly imposed upon, in our author’s phrase, we conceive it to be one of the greatest mistakes he has fallen into, as we shall shew in our next article; but

* M. Benoiston de Chateaufneuf in the *Annales d’Hygiène* for Jan. 1839.

it would be cruel to deprive our readers of a rich bit of the Malthusian language, with which we will conclude the present one. After shewing that the number of patients at the Dispensary has not fallen off much during years in which trade has been good, our brother of Sheffield says, "A taste for charity is created, and it will inevitably be gratified. Were the occasions greatly enlarged, the feelings would grow in a geometric proportion." This is pleasant, when we consider that a taste for charity in this instance means a taste for jalap, tartar emetic, and asafoetida!

CLINICAL LECTURE,

*Delivered at University College Hospital,
March 28, 1839,*

BY SAMUEL COOPER,
Senior Surgeon, &c.

GENTLEMEN,—I wish to bring under your consideration this morning three interesting cases: one of strangulated hernia, which required an operation; a second, of suppuration upon and under the dura mater, from an injury of the head, attended with symptoms that induced me to have prompt recourse to the trephine; and a third, of diseased hip, complicated with extensive abscesses, and dislocation of the head of the femur on the dorsum of the ilium.

In the description which I shall give of each of these cases, you will find some points of considerable interest to the practical surgeon, such as every gentleman desirous of excelling in his profession will deem well deserving of a place in his recollection.

CASE I.—Oblique Inguinal Hernia of fifty years' duration, and very large size, strangulated—Operation—Hernial sac divided into separate compartments, &c.

James Bull, æt. 63, a gonty subject, admitted February 28, at ten o'clock P.M., with a strangulated serotal hernia on the left side. He had been subject to the descent of the parts for 50 years; but they had in general been reduced without much difficulty. They came down, however, about three o'clock to-day; and the surgeon under whose care he was, having re-

peatedly tried the taxis in the course of the day without success, now sent him to the hospital. Two or three scanty evacuations from the large intestines had been obtained by means of an injection.

On the man's entrance into the hospital the hernia was very large, nearly equal in size to a man's head, tense, and slightly elastic, but with a dull sound on percussion, as if much fluid or fecal matter were contained in it. The weight of the swelling was considerable, and its neck tense and hard. The testes were situated below the tumor, and the left vas deferens could be felt under the skin, to the left of the rest of the spermatic cord. The patient was occasionally sick, and experienced a good deal of pain in the swelling, and in the abdomen.

The taxis and warm bath having been tried again, and proved ineffectual, I held a consultation with Mr. Quain, and it was determined that the best chance of saving the man's life would be by performing the operation before peritonitis came on; and after dividing the tendon of the external oblique, to reduce the bowels, if possible, without opening the hernial sac.

I made therefore an incision, three inches in length, in the direction of the neck of the hernia inwards and downwards, dissected down to the abdominal ring, and easily passed a director between it and the investments of the hernia. On this instrument the tendon of the external oblique was divided to the extent of about three-quarters of an inch. Having secured both ends of the superficial pudic artery, which was large and bled freely, I made every endeavour to reduce the viscera without opening the sac; but neither I nor Mr. Quain found it possible to accomplish this purpose.

I therefore opened the hernial sac with the usual precautions; and, this having been done, nearly a pint of serous fluid gushed out. A large piece of thickened omentum was now exposed; and, on holding it aside, the bowel presented itself, which, owing to its quantity (five feet), was not reduced without difficulty. With the able assistance of Mr. Quain, however, this was at length effected. The part of the protruded bowel last reduced was of a dull chocolate colour, but the remainder retained its natural appearance.

The question then arose, what ought to be done with the thickened omentum? I might have tried to reduce it; but there would have been some difficulty in doing this; and perhaps, after the reduction of the mass, inconveniences might have resulted from it. I might have left the whole of it down in the wound, in the expectation that most of it would have

gradually dwindled away, and the parts have healed over the remainder. I might have cut away the greater portion of it, then tied the bleeding vessels with silk ligatures, and reduced the upper part of it into the cavity of the peritoneum, cutting off the halves of the ligatures, and leaving the ends of the other halves hanging out of the wound. As this last plan would have been attended with some risk of effusion of blood into the abdomen, I decided to cut off the omentum near the upper part of the hernial sac, tie the bleeding arteries with fine silk ligatures, and leave the omentum in the neck of the sac undisturbed. By this means all possibility of a bleeding into the cavity of the peritoneum was obviated, and no large mass of omentum was left down to interfere with the process of cicatrization. Several of the omental arteries required ligatures, and after these had been applied, and half of each cut off, the remainders of them were gathered into a bundle, and left hanging out of the wound.

Wet lint was laid over the wound, and a compress and spica bandage put on. An enema was now administered, which was soon followed by two or three copious motions, and the patient passed a tolerable night.

March 1.—10 A.M. pulse 96, full and wiry; some pain in the abdomen, increased by pressure.

Twelve leeches to abdomen; fomentations; 5j. of Sulphate of Magnesia, in 3j. of Mint water every hour. An enema.

10 P.M.—Has had two motions. Pulse 92, softer, but intermits.

2d.—In consequence of there having been a good deal of pain in the abdomen in the early part of the night, a blister was applied. Bowels open.

3d.—Pulse 70. From this period the patient went on, with some fluctuations in his condition, tolerably well, with tonics, full diet, ale, porter, wine, &c., till the

20th.—Complains now of great pain in the chest, and frequent cough. Bowels open yesterday; pulse 100; thirst.

Blister to chest, and cough mixture.

21st.—Worse; has had no sleep; has subsultus tendinum; wound healing; bowels open. A swelling in the scrotum was suspected to be a portion of bowel that had slipped down again; but there were no symptoms of strangulation. The part, whatever it might be, was irreducible.

22d.—Died at three this morning, twenty-three days after the operation.

Post-mortem appearances.—Wound healthy, and omentum in it covered with granulations. *Chest:* serous effusion in the cavity of each pleura; 3vj. on right side;

3viij. on left, together with inflammation and deposit of lymph in the latter. Pneumonia of the upper two-thirds of the right lung, with hepatization. Petechial ecchymoses in the surface, and vesicular and interlobular emphysema of the lower third. In left lung pneumonia less extensive, but both kinds of emphysema throughout it.

The mucous membrane of bronchial tubes much injected and inflamed, and covered with copious mucous-purulent secretion.

Heart.—Serous fluid in the pericardium. Heart somewhat hypertrophied. Ossification and extensive disease of the aortic valves, with dilatation of the ascending aorta.

Abdomen.—Omentum drawn into folds towards the left groin, where it was adherent to the external wound. About five feet of the ileum, above the cæcum, was of a darkish slate colour, and presented dark brown patches, from congestion. At one point, two feet from the cæcum, the ileum was adherent to the left groin by a membranous band. No signs of active inflammation in any part of the abdomen. A few serous cysts on surface of kidneys. Prostate gland enlarged to the size of an orange.

Hernial sac.—In the scrotum, just below the wound, there was a tumor of about the size of a large apple, which, to the touch, seemed very like a loop of intestine, distended with fecal matter. On dissection, it proved to be a cyst, partly distended with a serous fluid, and containing a thin septum, so as to form two distinct cavities. These were produced by a part of the old hernial sac remaining hollow, and adhesions taking place between two prominent folds of it, so as to constitute the septum.

From the groin down to the cyst, the sac was puckered and drawn into folds, and all trace of any cavity obliterated by organized lymph; which, however, was so easily broken through, that the handle of the scalpel could be passed from the above-mentioned cyst into the abdomen.

REMARKS.—This case, gentlemen, appears, then, to be one in which the immediate cause of death was principally thoracic inflammation; and the state of the parts connected with the former hernia, perhaps, had little or nothing to do with the fatal termination. All his pain and suffering before death were referred to the chest, and none to the abdomen.

Experience proves that numerous deaths after surgical operations, gun-shot wounds, and other mechanical injuries, are brought on by severe inflammation occurring in

internal organs remote from, and seemingly unconnected with, those which form the seat of original injury. This sometimes is explicable by the effects of phlebitis, but in such case deposits of pus take place in the viscera, synovial membranes, and other textures.

But after operations and bad mechanical injuries, like gun-shot wounds, many patients are cut off by visceral inflammation excited in another way, as particularly adverted to by Dupuytren, in his valuable remarks on gun-shot wounds. It is where from the reduced state of the patient we are led to allow him an abundant diet, with wine and other cordials, on the approach to convalescence or a cure. This sometimes creates a tendency to visceral congestion and inflammation, whereby the patient may be cut off just in the stage when the greatest hopes of a perfect cure are entertained. I offer this remark, however, in relation to our case, only as a conjecture; but were another case, resembling the foregoing, to come under my care, I should feel disposed to prescribe a smaller quantity of wine and a more limited diet. The subject, however, is a difficult one; for, on the one hand, unless the patient be duly supported, he sinks from debility; and on the other, if he be stimulated and fed too much, he dies of visceral inflammation.

CASE II. — *Penetration of the Skull and Membrane of the Brain by a Nail.—Suppuration under the Bone.—Trepphine.*

Frederick Rudd, æt. 12, admitted March 14, 1839. About three weeks prior to this date, a door fell on his head, and a nail which projected from it penetrated through the right parietal eminence. He was not completely stunned by the blow, merely experiencing a little giddiness. Around the wound it seems that an effusion of blood under the scalp ensued, producing a swelling of about the size of a pigeon's egg. The hair was cut off the part, a leech was applied, by the direction of the practitioner first called in, and some aperient medicine given. For ten days after this he appeared to be well, playing and taking his food as usual.

About the eleventh day after the accident he began to lose his appetite, complained of pain in his head, and was sick. These were the first symptoms of mischief within the cranium. On the sixteenth day he became delirious; but this state subsided after the administration of a dose of jalap.

On his admission into the hospital, there was a small wound over the most prominent part of the parietal bone, of a size just sufficient to admit a quill. Around this the integuments were some-

what swollen and puffy, and from the wound itself some foetid purulent matter exuded. It was found that a probe could be passed through the aperture in the skull, so as to touch the dura mater. Pulse 100; tongue white; skin hot; pupils dilated. Some stupor and drowsiness, but the intellects, in other respects, little affected. Frequent vomiting of bilious matter. Severe pain in the right side of the head, and across the forehead.

Three grs. of calomel every six hours.

Scalp to be shaved, and evaporating lotion applied.

I o'clock.—As the symptoms continued, and they indicated suppuration under the parietal bone, I made a crucial incision; and the flaps or angles were reflected, together with the pericranium. Some free hæmorrhage followed, and nearly half a pint of blood was lost. A small oval aperture in the prominent part of the parietal bone was thus brought into view; and I noticed that some foetid matter lay on the outside of the bone. A portion of the parietal bone, of the size of a shilling, was sawn out with the trephine, so as to expose the dura mater, which had a darkish colour, was thickened, and covered with a layer of purulent matter, which was sponged away. There was also some pus adhering to the inner table of the circle of bone taken out. Pus was also noticed to issue out of the small aperture made by the nail in the dura mater. This I did not see myself; but it is not improbable that pus lay under this part of the dura mater, because the pulsatory movements of the brain were not perceptible within the perforation made with the trephine.

Cold evaporating lotion applied, and a saline antimonial mixture ordered, with Calomel gr. iij. every six hours.

Without entering into further details, I may state, that, with the exception of a slight degree of diplopia, and a little sickness occasionally taking place after meals, and excited probably by the tartarized antimony, this case went on most favourably, and the boy has since been discharged perfectly cured, and with his vision in every respect right again.

REMARKS.—It is an universally approved maxim in surgery, that whenever purulent matter lies close upon, or compresses, or disorders the functions of an important organ, a free outlet for such matter should be made without delay. The febrile symptoms—the headache, stupor, and dilated pupils—the puffy swelling of the scalp—the manner in which the skull had been struck and perforated by the nail—the probability even that the inner table might be splintered—all these

considerations led me to believe that supuration of the dura mater had occurred, and that, unless a free outlet for the matter was promptly made, the boy would have little or no chance of recovery.

Here I deviated from the rule which is always inculcated in my lectures, that the trephine cannot often be applied with benefit while the patient retains the power of voluntary motion—retains his intellectual faculties—and is not afflicted with urgent symptoms of pressure. But exceptions to this maxim are recognized; and one of these is the case of suppuration of the membranes of the brain. You may also be justified in trephining what is termed a punctured fracture, to the nature of which this accident approximated, because you will find, though it did not happen in this instance, that, in the generality of cases, the inner table is splintered and depressed, and the early removal of such splinters is the best way of preventing dangerous consequences.

Dislocation of the Head of the Femur, from Disease of the Hip-joint.

Henry Warburton, æt. 15, admitted on the 21st of January—an emaciated boy, of hectic appearance. About five weeks before this period, he met with a fall, to which he imputed the origin of his complaint.

On his entrance into the hospital, the limb was about two inches shorter than the other, and the toes and knee were inverted, with the head of the femur lying on the dorsum of the ileum. He laboured under hectic fever, and had profuse nocturnal perspirations. The disease began with severe pain in the knee, as well as the hip.

A few days after his admission, an abscess was perceptible around the joint. I punctured this collection of pus, and let out a quantity of foetid bloody matter, and from the opening thus made a copious discharge continued so long as the boy lived. Notwithstanding the administration of tonics, and the allowance of a generous diet, with porter, &c., he sunk, as had been anticipated; his death taking place on the 11th of March.

In the *post-mortem* examination, the head of the femur was found on the dorsum of the ilium, directly above the acetabulum, and on the upper border of the sciatic notch, in the centre of a vast abscess, which extended through this notch into the lower pelvis. Here the pus was shut out from the peritoneal cavity by the obturator fascia and peritoneum. In front, the abscess had passed upwards under the psoas and iliac muscles, so as to occupy the iliac fossa, but without communicating with that part of the abscess already de-

scribed, and which extended into the pelvis through the sciatic notch. The brim of the acetabulum was obliterated, and the cavity itself filled up partly with a fungoid mass, and partly with firm coagulating lymph. The brim of the acetabulum was rough and gritty, and the os ilium above the acetabulum destitute of periosteum. The head of the femur had lost most of its cartilaginous investment, and was carious and irregular at various points.

WESTMINSTER MEDICAL SOCIETY,

Saturday, April 27, 1839.

W. D. CHOWNE, ESQ. M.D. IN THE CHAIR.

Financial matters.—Destruction of the Cornea in Small-pox.—Poisoning from drinking an excessive quantity of Gin.

THIS being the last meeting for this session, arrangements were made for collecting the subscriptions, which, according to the recent law, would be due from every member who was desirous of not detaching himself from the society. Several gentlemen paid up their subscriptions at once, and Dr. James Johnson made, in addition, a present of ten guineas to the treasury. It is earnestly requested by the committee that members would, as soon as possible, signify to either of the presidents (Dr. Chowne or Mr. Thomson) their adhesion to the society, and at the same time forward their annual rent, which should be paid in advance.

Power has been given to the committee to seek for a more eligible place of meeting for the next season, so that the comfort of the members may be well attended to, which was an impracticable task at the Hunterian Museum.

Mr. Marson now read an excellent paper on the cause of the destruction of the cornea which occurs after small-pox, which we gave entire in the pages of the *MEDICAL GAZETTE* last week. He satisfactorily confuted the common error that the destruction is due to the occurrence of a pustule on the cornea; and proved, we think, unanswerably, that the disease originates in the cellular tissue which unites the several laminae of this tunic, and which, as it possesses many of the same qualities, and performs the same functions, as the same tissue in other parts of the system, may justly be considered as liable to the same maladies.

Dr. Chowne finally related the particulars of an interesting case of poisoning from gin. A young boy being left alone

in a room, swallowed in the course of half an hour the contents of a stone bottle, containing about a pint and a half of this spirit. In about a couple of hours he was perfectly comatose. the pupils were contracted and insensible, and the expression of countenance perfectly stolid. The limbs were completely inert, the pulse slow, and the respiration about twelve per minute. Ammoniacal stimuli were administered, and in a few hours the expression of face became more intelligent, but consciousness was not restored, and the temperature of the surface remained low. The respiration became quicker, and the pulse rather more powerful. After sixty-three hours he died. The body was carefully examined. In the brain the veins were rather turgid, and the pia mater was marked with opaque spots. The choroid plexus also was injected. Nothing remarkable was detected in the other parts of the encephalon.

In the thorax there was nothing worthy of note, except an effusion of frothy mucus into the air-passages of the lungs. The heart was quite normal. In the abdomen and pelvis, no appearance could be detected that was worthy the attention of the medical jurist. Dr. Chowne promised to publish the case.

Dr. James Johnson stated, that the symptoms detailed by Dr. Chowne, as well as the post-mortem appearances, exactly corresponded with the symptoms and appearances produced in animals by division of the pneumo-gastric nerves.

Mr. Snow related the particulars of one or two experiments on dogs and cats, which tended to corroborate the opinion of Dr. James Johnson. After the discussion, the society concluded its session. The reporter cannot close his remarks without expressing how much pleasure and instruction he has derived from the discussions carried on in this society during the present session, and from no one of which has he been absent; as well as avowing the hope that he shall be enabled to continue his agreeable task next year.

IBIOS.

DR. CORRIGAN.

DR. CORRIGAN has been appointed physician to his Excellency Lord Ebrington.

MR. S. COOPER AND MR. LIFTON.

WE have received from both the gentlemen above named, copies of a correspondence which has passed between them. Mr. Cooper's came first to hand, and we have given directions for placing it in the *extra limites* department, not wishing it to interfere with the ordinary contents of the number.

COLLEGE OF SURGEONS.

Prevailing wind, N.E.

Except the 2d and evening of the 8th, generally clear.

From about half-past seven in the evening of the 8th till about midnight, a terrific thunder-storm, accompanied by the most vivid lightning and heavy rain; from in night till about two in the morning of the 9th, distant thunder and lightning; thunder also on the afternoon of the 2d.

Rain fallen, .5125 of an inch.

CHARLES HENRY ADAMS.

WILSON & SON, Printers, 57, Skinner-st., London.

(EXTRA LIMITES.)

No. I.

To the Editor of the Medical Gazette.

SIR,

THE following correspondence has passed between Mr. Liston and myself, respecting the contents of a letter of mine in your last number. In addition, it is to be observed, that the editor of the *Lancet*, in his number of the 4th instant, has subjoined to Mr. George's candid and honourable letter, a shuffling note, in which he virtually admits, that the trickish heading of the article, and also the "interpolations," were introduced by an individual hired by and acting under him. It follows, then, that Mr. Liston is also absolved, by the confession of the guilty party himself, from all share in this disgraceful transaction. Whether this slanderous editor actually introduced the false heading and interpolations himself, or suffered them to be introduced by the reporter whom he pays (not Mr. Borthwick be it remarked) is a point which the profession, who already know his editorial transgressions well, will not deem an inquiry worth pursuing.

In fairness to Mr. Borthwick, I have enclosed his letter to me.—I am, sir,

Your obedient Servant,

SAMUEL COOPER.

Woburn Place,
May 7th, 1839.

P. S.—You will oblige me much by letting these documents appear in the next number of your valuable journal.

No. II.

12, Old Burlington Street,
May 4th, 1839.

Sir,—I find in the *MEDICAL GAZETTE* of this day a letter bearing your signature, and addressed to me.

The appearance of this letter, after the conversation which I had with you on Monday last, cannot but surprise me. There must have been some mistake on your part as to what Mr. Borthwick said in regard to the notes of cases. He copied

the one in question, and many others, for my private use and for my clinical lectures, and this day's number of the journal which contained the original report publishes my disavowal of any connexion with it.

With this explanation, and the most positive contradiction of the allegations contained in your letter in the *MEDICAL GAZETTE*, I trust you will see that it is due more to *your* character than to *mine*, that you should withdraw your charges, and express your regret for having made them.—I have the honour to be, sir,

Your most obedient servant,

ROBERT LISTON.

Samuel Cooper, Esq.

No. III.

Woburn Place, May 6th, 1839.

Dear Sir,—On my return to town this morning, I found your letter of the 4th instant.

After the explanations which your letter contains, and your positive disavowal of all connexion with the article inserted in the *Lancet* of April 20th, I fully acquit you of all participation in the transaction which I complained of in my letter to the Editor of the *MEDICAL GAZETTE*, dated the 27th of April. I cannot, hesitate, therefore, one moment in the expression of my regret at the insertion of my letter in that journal, so far as you are concerned. I regret, too, that the explanation did not take place earlier, which would have prevented me from bringing the matter before the public.—I am, dear sir,

Yours very truly,

SAMUEL COOPER.

To Robert Liston, Esq.

P. S.—Mr. Borthwick wrote to me on the 2d of May, to say that the case of John Fagan, which he transmitted to you, and which he copied from the hospital case-book (perhaps with some "verbal alterations"), did not contain any allusion to me.

No. IV.

12, Chadwell Street, Myddleton Square,
May 2, 1839.

Sir,—Understanding that some one has been so obliging as to inform you that I was the author of the scurrilous paragraph referring to you, in the *Lancet* of 20th April, I feel bound, out of justice to myself, to address you upon the subject.

In the first place, I distinctly and unhesitatingly deny that I either inserted, or was in any way party to, the insertion of the sentence commencing with the words, "It is strange," &c. and terminating with, "Oh, sir! Mr. Cooper put that in," occurring in the second column of page 160 of that number of the *Lancet*. It is quite true that I reported the case in which that statement occurs; but the paragraph alluded to is a gross interpolation. I copied the case, as I am in the habit of doing, from the case-book; and though I often make verbal alterations, I can assure you I never travel out of my way to introduce extraneous matter, for the purpose of maliciously and falsely slandering the character of any individual, far less one of the professors under whom I have the honour to study.

And now, sir, in the second place, I must trouble you with a few cursory remarks on the conduct of the gentleman (whoever he be) who was so kind as either directly to state, or indirectly insinuate to you, that I was the author of the impudent and barefaced lie; for though the words, as reported, are very similar to those made use of by the patient on the operating table, still it must be evident to all, that by omitting the explanation which he appended, that "it was not you that he meant," — it was the unequivocal intention of whoever introduced the paragraph, to mislead the public; and is, therefore, as much a lie *morally*, as if an absolute false *verbal* statement had been made.

If, sir, that gentleman, like the great proportion of the students at the hospital, only suspected, from a vague report, that I was the author of J. F.'s case, and, with-

out taking the trouble of inquiring how far that report was correct, made a statement to you, tending to injure a fellow student in your eyes; then, to say the least, he has been guilty of a very unpardonable indiscretion.

But if, again, sir, he knew that *positively* I was the author, as he could only come at that information by having heard me acknowledge myself so, which I did several times, each time, however, stating clearly, I neither introduced nor knew anything of the introduction of the offensive paragraph; then, sir, by pursuing the course he has done, by keeping back the most essential part of his information, and wilfully misleading you, he, too, has been guilty of an action as mean as it is detestable, and which he might well blush to own, if, indeed, that mark of not altogether extinguished honesty has not long been a stranger to his face.

Expressing my sincere regret that such circumstances should have arisen, calling for such a letter from me to you, sir, I have the honour to remain, sir,

Yours respectfully,

WM. THOS. BORTHWICK

To Samuel Cooper, Esq.

In my answer I assured Mr. Borthwick that nobody had insinuated to me anything against his conduct in this affair, nor did I ever entertain any doubt about his upright principles. Mr. Borthwick's letter is important, as justifying, at least in some events, some parts of my letter of May inserted in this journal. This last letter (containing the grounds of my suspicion against one party or another, and no party whatsoever), before being dispatched for publication, was read to Mr. Liston in the presence of Dr. Carswell and the Secretary of the Hospital, in the afternoon of the 29th ultimo, in order to afford him the opportunity of explanation; but he refused to do so, and contented himself with saying that he had had nothing to do with the affair.

LECTURES
ON THE
CHEMICAL HISTORY, PATHOLOGY, AND
MEDICAL TREATMENT
OF
CALCULUS,
AND THE VARIOUS DISORDERS OF THE
URINARY SYSTEM.

By DR. VENABLES.

Of Urinary Gravel and Calculi.

The ammonio-phosphate of magnesia, or triple calculus.—This calculus—of which I here present you several varieties, and of which you will find a very good representation in plate viii. fig. 5, of Dr. Marcet's work—is commonly of a white colour; surface uneven, and covered with minute shining crystals. It is not like the foregoing, of a laminated texture; but it is easily broken and pulverizable. In a few instances it has been found very hard and compact; and, if broken, it exhibits a crystalline texture, the crystals being interspersed between the layers of other calculeous matter; and it is often more or less transparent*. The form of the crystals, according to Dr. Wollaston—to whom we are so much indebted for what we know of calculi—is that of a short trilateral prism, having one a right angle, and the other two equal, terminated by a pyramid of three or six sides. Calculi consisting wholly of the triple phosphate are extremely rare; but concretions in which this greatly predominates occur frequently.

Chemical characters.—Before the blowpipe this calculus first becomes slightly

discoloured, and gives off the smell of ammonia (still more sensibly if a little potass or soda be previously added), owing to the disengagement and volatilization of this principle. The fragment at the same time diminishes in size, and ultimately fuses or melts into a sort of whitish or cloud-like enamel. The fused mass is the phosphate of magnesia, with excess of phosphoric acid, owing to its being deprived of the ammonia; and it is to the excess of acid that the fusibility is to be attributed. Berzelius recommends the following blowpipe analysis for the dry or solid phosphate, with the view of determining the presence of phosphoric acid, and which I have very frequently practised in the last-mentioned calculus, the one immediately under consideration, and the next for consideration; and which I shall now proceed to explain and exemplify.

The assay is to be fused upon charcoal, by mixing it with boracic acid and fusing it. When the fusion is complete, we plunge the point of a fine steel wire through the fused bead, and longer than the diameter, so that a portion of the wire shall project on either side of the globule. The globule—as you thus see it—is withdrawn on the wire, and now strongly heated in a good reducing flame—thus. The iron becomes oxidated at the expense of the phosphoric acid, and borate of protoxide of iron and phosphuret of iron are the results of the decomposition. The phosphuret fuses at a pretty high temperature, and the assay, which at first, as you saw, was spread out over the whole length of the wire, after heating has resumed the globular form. As the globule cools, an appearance of ignition may be generally observed near its base, which arises from the crystallization of the phosphuret of iron. The globule is now to be separated from the projecting wire, wrapt up in paper, and struck gently with a hammer

* Prout on the Urinary Organs, p. 90.

on the anvil, by which the phosphuret of iron is separated, and appears in the form of a brilliant metallic globule, attractable by the magnet—as you see; and so brittle that it springs to pieces when struck with a smart blow of the hammer—thus. The fracture, as you observe, is steel-coloured. The brittleness depends on the proportion of the iron; sometimes it may be only a little flattened under the hammer. If the assay contain no phosphoric acid, the steel wire will burn only at the ends which project beyond the globule, preserving its brilliancy in the other parts. To insure success, also, the assay must contain rather more than five per cent. of phosphoric acid, as less than this proportion is insufficient to fuse a mass of iron as large as the experiment requires, to prove unequivocal; neither will it prove unequivocally the presence of phosphoric acid, if the assay contain arsenic, or sulphuric acid, or metallic oxides, as then we should obtain compounds of their bases with iron; and therefore the presence of substances capable of reduction by iron, and of fusion into a globule with it, would invalidate the test*.

If this calculus be heated with solution of caustic potass in a platinum or silver capsule, ammonia is disengaged, known by the odour. If this be performed in a glass tube, a slip of moistened turmeric paper is turned brown; or if reddened and moistened litmus paper be used, the blue colour of the litmus is restored by the escaping ammoniacal gas. This calculus also is readily dissolved by diluted acetic, hydrochloric, or nitric acids; and reprecipitable by ammonia without decomposition. These characters are quite sufficient to identify this calculus, and to determine its composition.

Calculus composed of a mixture of the two foregoing—the phosphate of lime and ammonio-phosphate of magnesia—or fusible calculus.—This calculus, frequently named the mixed phosphates, is whiter and more friable than any of the other species, sometimes resembling a mass of chalk, and leaving a white dust on the fingers. This species is not, generally speaking, laminated, and appears in the form of a spongy, friable,

whitish mass, in which the laminated structure is not obvious; and a representation of which you may see in the seventh plate, fig. 2, of Dr. Marcet's work. It sometimes, however, readily separates into laminae, the interstices of which are studded with sparkling crystals of the ammonio-phosphate of magnesia. That variety which is not laminated often attains a very large size, and then moulds itself to the contracted cavity of the bladder, terminating at its broader end in a kind of peduncle, corresponding to the neck of the bladder, as delineated in fig. 1, plate vii. of Marcet's work, as you see—a peculiarity of form which Dr. Marcet states he never observed in any of the other species of calculi. This kind of calculus occurs very frequently, and it often gives an external coating to lithic calculi, as you may observe here.

Chemical characters.—Before the blow-pipe this calculus readily melts, and the fusion is very easily effected, as you see in this instance. It readily dissolves in dilute hydrochloric acid. Its composition may be shown by various methods. If, for instance, it be pulverized, and then acted on by very dilute sulphuric acid, of specific gravity not exceeding 1020, the ammonio-phosphate of magnesia will be dissolved, and the phosphate of lime will remain behind, being scarcely acted upon by sulphuric acid of this tenuity. A preferable plan, however, is to digest the pulverized calculus in somewhat diluted acetic acid, the triple crystals will be dissolved, while the phosphate of lime will not be affected. The phosphate of lime, which is contaminated with a small proportion of lithic acid, may be separated from this impurity by dissolving it in a little diluted hydrochloric acid, which acts upon the phosphate, leaving a residue which consists of lithic acid. The calcareous phosphate may be recovered by saturating the hydrochloric acid by potass or soda, when the earthy salt will precipitate, and its characters may be determined, as has been already pointed out.

The ammonio-phosphate of magnesia may be precipitated from the acetic solution by carbonate of ammonia, and recognized by the properties forming a specific distinction. With respect to the lime, it may be separated by the plan formerly pointed out, of converting the phosphate into carbonate by boiling with carbonate of potass, and thus decomposing it; the resulting carbonate of lime may be readily distinguished. Or the lime may be precipitated from the muriatic solution of the phosphate by adding oxalate of ammonia, the lime precipitates as an insoluble oxalate, which may afterwards be reduced to the caustic state by heat, as already explained.

* Berzelius on the Blow-pipe, translated by Children. If phosphate of lime be decomposed by boiling with carbonate of potass, and the resulting phosphate of potass be decomposed by nitrate or acetate of lead, a phosphate of lead, which is wholly insoluble, will precipitate; and this presents specific characters. Thus it is almost wholly insoluble in free acetic acid—as you see. If the precipitated phosphate of lead be dried, and then fused upon charcoal in the outer flame of the blowpipe, the fused mass becomes distinctly crystalline upon cooling, as you can now see in the experiment I have just performed. For this test we are also indebted to Berzelius. (*Anwendung des Löthrohrs*).

The magnesia may also be obtained by various means. For instance, the calculus may be dissolved in hydrochloric acid: the lime may be precipitated by sulphuric acid, which, if in excess, will retain the magnesia in solution; from which, after being filtered, the magnesia may be precipitated by carbonate of soda, when it may be easily recognised by its various properties. There is no difficulty in proving the presence of the ammonia, for if heated with potass or soda, ammonia is disengaged, and manifested by its pungent odour and alkaline reaction. We may thus prove the basic composition of this substance.

With respect to the phosphoric acid, this may be detected, as already pointed out, by decomposing the phosphates by boiling with carbonate of potass, and testing the resulting phosphate of potass by the nitrate of silver, as before pointed out. Dr. Marcet observes:—The presence of phosphoric acid may also be shewn by reducing it to the concrete state by the blow-pipe, on a slip of laminated platina; the acid, when thus urged, communicating to the flame a peculiar green tinge*. Perhaps the better mode for the oxalate of lime, and the earthy phosphates, the best mode of identifying the acids would be to decompose them by an alkaline carbonate; treat the resulting alkaline, oxalate, or phosphate, as the case may be, with a neutral solution of nitrate or acetate of lead; collect the precipitated oxalate or phosphate of lead, wash, and finally suspend in distilled water, and pass through hydrosulphuric acid gas: sulphuret of lead will be precipitated, and the acids liberated will be found dissolved in the water, and in a state of very great purity†; when they can be recognized very satisfactorily by their distinctive properties. In the tubes and jars which I hand round in this small tray, you have the results of all the various stages of the different processes; and by referring to the letters and numbers in the manuscript key, you will see what particular stage of the operation each exemplifies.

* On Calculous Disorders, p. 6.

† It appears to me, that the process adopted by the College for the formation of phosphorin, is both troublesome and complicated, and that the following, as less so, and also less expensive, might be advantageously substituted:—Act upon calcined bones by diluted sulphuric acid; by which we shall have sulphate of lime precipitated, and superphosphate of lime in solution: precipitate the phosphoric acid by acetate or carbonate of lead. The phosphate of lead, suspended in distilled water, may be decomposed by hydrosulphuric acid gas, and the liberated phosphoric acid concentrated by distillation or evaporation, and brought to the required strength by water. Or the required concentration may be obtained at the first operation, by suspending and decomposing the metallic phosphate in the equivalent quantity of water; filtering and boiling, to expel the excess of hydrosulphuric acid gas.

The next two species are what have been termed compound calculi, from the nature of their composition. They comprehend the alternating and the mixed species.

Alternating calculus or compound calculus in distinct layers.—The composition of this calculus consists of some of the former species, disposed in layers, and around a common nucleus. Thus we sometimes find a lithic nucleus surrounded by an oxalate of lime deposit, or the lithic may alternate with the phosphates. In some cases the mulberry alternates with the phosphates, and in some cases we find three or even four species of calculi deposited in distinct concentric laminae. Here are some examples; and in these figures of the sixth and seventh plates of Dr. Marcet's work, there are good delineations of these different varieties; and in this figure (plate viii.) we have a delineation of a calculus consisting of four distinct species, disposed in successive or alternate layers: for instance, in the centre is the lithic acid; next to this, pure striated phosphate of lime; external to the latter, is a mulberry or oxalate of lime deposit; and external to all, is a crust of the fusible calculus enveloping the whole concretion. From these facts, it must be evident that the characters of the compound calculi will vary with the nature and extent of their composition. Mostly, however, they consist internally of a lithic or mulberry nucleus, and an external crust of the fusible phosphates; and, indeed, the fusible phosphates, in most cases, seem to constitute the ultimate result of all the varieties of the calculous diathesis.

Chemical characters.—With respect to these, it is evident they also will vary with the composition. When sawn through, with a round-headed or a broad-edged file (varieties of which I here shew you), a portion may be thrown down, pulverized from any portion internal or external, or of any intermediate portion, and then examined by the means already described, and the composition determined.

Mixed calculi, or calculi with their ingredients intimately intermixed.—Calculi of the above denomination, if *abstractedly* considered, would comprehend almost every species, for there are but few urinary concretions which do not give evidences of the principal components of urinary calculi. Indeed there are very few that do not, upon examination, afford some traces of lithic acid and of the phosphates. But the species which we are now about to consider have not the individual species in distinct layers, as those we have just examined, but they are found intimately intermixed, as if all thrown down at

once, from a general solution in an amorphous state, by the simultaneous action of the various re-agents, and then conereted into a calculus mass. "Mixed calculi," says Prout, "consist of an intimate mixture of any two or more of the preceding species; but generally of a mixture of the lithate of ammonia and the phosphates." Dr. Marcet confines the term compound calculi, with their ingredients intimately mixed, to "those substances alone which have no characteristic feature by which they may be considered as belonging to any of the other classes." The colour of such calculi is indeterminate, for it varies with the composition. Their figure is for the most part irregular, nor are they distinctly stratified, and they possess considerable hardness. They are very seldom of large size, and fortunately are very rare.

Chemical characters.—These calculi are chemically characterized by the confused or rather ambiguous results derived from some of the preceding modes of examination. These, however, with the general appearance, will enable us to form an opinion as to the mixed nature of the composition. Suspecting, then, a calculus to consist of the mixed ingredients, we must proceed to separate the component principles, and examine them in detail. First, then, we must finely pulverize a portion of the calculus, and subject it to the action of hydrochloric acid: this will dissolve the phosphates, leaving behind the lithic acid; or, perhaps, the better plan would be, digestion in dilute acetic acid, by which we should remove the triple crystals, leaving the phosphate of lime with the lithic acid. Diluted hydrochloric acid will now dissolve the phosphate of lime, and leave the lithic acid behind, which may be dissolved in caustic potass after the other principles have been removed. To determine the presence of lithate of ammonia, we have merely to digest a portion of the finely pulverized calculus in a solution of carbonate of potass, when we shall obtain lithate of potass and carbonate of ammonia. From the solution the lithic acid may be precipitated by hydrochloric or acetic acid, and upon the evaporation of the mother water, we shall obtain hydrochlorate or acetate of ammonia. Here I present you an amorphous precipitate, obtained by acting on different urines by the various reagents, collecting the precipitates and mixing them intimately by agitating them altogether, so as to suspend them in distilled water, allowing them to subside, and collecting the sediment. By acting on this first with carbonate of potass, I removed the lithate of ammonia which you see here. By caustic potass the free lithic acid was next removed—a portion

of which you see here; and by diluted acetic acid the ammonio-phosphate of magnesia was separated; we then left a mixture of phosphate and of oxalate of lime. These may be separated by tolerably concentrated acetic acid, which dissolves the phosphate, but leaves the oxalate unacted upon. Thus it is that every principle of a urinary calculus may be readily identified and determined by a little industry and adaptation of the different modes of investigation to the objects we have in view.

Cystic oxide calculus.—This calculus is extremely rare, and we are indebted to Dr. Wollaston for calling our attention to it as a peculiar species. His paper was published in the Philosophical Transactions for 1810. The specimen which first came under his observation he received from Dr. Reece, of Norwich, and shortly after he discovered another specimen in the collection at Guy's Hospital*.

In external appearance, Dr. Wollaston states, "these calculi resemble more closely the ammonio-phosphate of magnesia than any other sort; but they are more compact, and do not consist of distinct laminæ, but appear as one mass confusedly crystallized throughout its substance. They have a yellowish semitransparency, and a peculiar glistening lustre, like that of a body having a high refractive density." This calculus is generally comparatively small: those which I saw at Guy's did not any of them surpass the medium size, and many of them were still smaller. I here exhibit half of a cystic oxide calculus, which I had not only the good fortune to meet with, but also an opportunity of frequently examining the urine of the individual who passed it. You see that it presents characters closely resembling those specified. In the present instance, you see it is of a dull whitish colour; of a confusedly crystalline appearance, and, in very small fragments, it is to a certain extent transparent. Sawed through, it has the consistence of wax. Thus, in sawing through the specimen of which I shew you, the teeth of the saw became clogged up, as it were, with wax. This calculus also is frequently studded externally with crystals of the triple phosphate, for which the calculus itself may be readily mistaken, and of which, at first, I presumed the present specimen to be a modification, till a chemical investigation awakened my attention to its singular peculiarities.

Chemical characters.—Before the blow-pipe, this calculus gives off a very pecu-

* There is a very beautiful and valuable collection of calculi, and excellently arranged, at Guy's, and to which Mr. Harrison very politely has allowed me access.

liar and characteristic odour, and quite different from that of lithic acid; nor does it at any period resemble that of prussic acid. I now heat a small portion upon a slip of platinum; and you now have an opportunity of examining and recognising this odour. It has something of a foetid animal odour, leaving a whitish ash, which is not alkaline; and the characters already enumerated would be in themselves quite sufficient to decide the nature of this peculiar substance. However, from its very ready solubility in both acids and alkalies, it was named "*oxide*," by its discoverer, Dr. Wollaston. As you see, it dissolves with equal readiness in the hydrochloric and nitric acids, and in solutions of potass, of soda, or of ammonia. Almost all the acids act upon it; the few which exert no agency, or at least very little, upon it, are from their limited number easily remembered. They are principally the acetic, citric, tartaric acids, and sesquicarbonate of ammonia. Therefore to recover it from its acidulous solutions we add a solution of sesquicarbonate of ammonia in sufficient proportion to saturate the acid, when it precipitates—as you see in the present instance. To obtain it, on the other hand, from its alkaline solutions, we use the acetic, citric, or tartaric acids—and in this example you see it set free and precipitated by the acetic acid.

Its solvents, indeed, are very numerous—as lime-water, barytic-water, and even the carbonates of potass and soda. Its solutions in the acids, if concentrated and evaporated, crystallize in slender spiculæ, running in radii, as it were, from a centre, something like what I here exhibit to you, and which readily dissolve again in water. The compounds which it forms with alkalies, on the contrary, crystallize in small granular crystals, such as you see in this glass capsule*. From its disposition to so readily combine with acids and alkalies, Dr. Wollaston named this substance, as already stated, an-oxide; and as in the only two instances in which it had then been presented to his notice it had been taken from the bladder, he named it "cystic oxide." But although instances of the occurrence of this calculus are extremely rare in comparison with most of the other kinds, yet several have been met with and described. Soon after Wollaston's discovery, Dr. Henry met with two in a collection of his own. Dr. Marcet met with three, the histories of

which are detailed at length in his work on Calculous Disorders, to which I refer you. Dr. Prout also mentions one or two instances; and I have given the history of the individual who passed the calculus which I have just shewn you. From all these, then, it would appear that this calculus is, like most others, of renal origin, and that the epithet "cystic" is so far a misnomer. But perhaps it is scarcely worth while to make any innovation upon the name which its discoverer first gave to it, even though that name be derived from a misconception of the origin of this substance; therefore we shall continue to designate it by the name originally given to it*.

LECTURES

ON THE

VENEREAL DISEASE,

*Delivered at the Aldersgate School of Medicine,
March 1839,*

By F. C. SKEY, F.R.S. &c.

LECTURE II.

ON THE COMMON VENEREAL SORE.

Summary of the doctrines inculcated in the previous lecture—Characters and progress of the common venereal—Its degree of elevation dependent on its situation—Probable identity of its poison with that of gonorrhœa—The venereal bubo—Treatment of venereal—Mercury unnecessary in the treatment of venereal—The venereal superficialis and indurata—Liability of the latter to slough—Treatment of sloughing sores—Summary.

In the last lecture, I introduced to your notice some preliminary questions of great interest, relative to the venereal disease. To two of these I wish now to return. The first is the immediate source of contamination; the second is the prevailing error on the subject of the prominent character of the venereal sore.

With respect to the former question, I told you that the evidence is incontrovertible—1st. That the precise form of venereal diseases, be they gonorrhœal or ulcerative, is not determined by the poison of the party infecting. 2dly. That a poison of any variety may be developed in an apparently healthy person, without

* Whether these crystals be formed from solutions in potass or soda, they should be kept hermetically sealed if we wish to preserve them—in the case of the potass, to prevent deliquescence, by the attraction of moisture from the atmosphere; in the case of soda, to prevent efflorescence, by parting with the water of crystallization.

* Some of the foreign writers have named this substance "cystine;" but this, as derived from the term cystic, appears equally objectionable. Dr. Marcet proposed to call it "renal oxide," and which is certainly the most appropriate, allowing the term oxide to be unobjectionable, which, however, perhaps is not altogether the case. Perhaps "nephrene" would be the least objectionable name.

the presence of disease of any kind in the party generating it (unless we are warranted in applying the term to the natural secretion of a part in excess; strictly speaking, possibly we are so warranted), at all events where there is no reason to suspect the presence of the disease given. 3dly. That certain forms of the so-called venereal disease are spontaneous, or self-generative, and arise in the person affected entirely independent of sexual intercourse.

A well-known case is mentioned by Dr. Fergusson, when speaking of the venereal diseases of Portugal, of a danzatrice belonging to the Opera at Lisbon, who indulged a penchant for the British officers at the commencement of the Peninsular war. Many of them were severely and incurably diseased, while she pursued her nightly career as a dancer, apparently undisturbed by disease of any kind.

Mr. Evans obtained the opportunity of examining a girl who had given three forms of disease to three different persons, and the girl had nothing beyond "slight leucorrhœa." As regards my own experience, I have seen so many examples of disease arising where I have the strongest reason to believe disease did not exist, that I cannot hesitate to express my thorough conviction of this important truth. If, therefore, I find a disease produced which had no existence in the person producing it, whence does the poison emanate? Undoubtedly its elements lie dormant in the affected party or parties, by or between whom it is developed by sexual intercourse, and presenting a form probably determined by peculiar constitutional liabilities.

Observe the detail of the following case, which I quote from Mr. Abernethy's "Surgical Observations on Diseases resembling Syphilis," the prominent characters of which are, I really believe, of most frequent occurrence:—

"A gentleman was connected with a female who was kept by another gentleman, and derived from such connexion several very irritable and foul sores, which broke out on the prepuce, but which, however, had not the syphilitic characters. As neither the woman nor her keeper had any disease, he had no wish to take mercury, nor had I, being consulted on his case, any desire to recommend it to him. The sores did not heal until between two and three months, though a variety of applications were employed. He at length, however, became perfectly well; and I cautioned him not to be again connected with the same woman. But his inclination got the better of his prudence, and another crop of sores, equally irritable, foul, and tedious, took place in conse-

quence of a second connexion. These sores were treated in the same manner as before, and slowly healed. After some lapse of time he again erred in the same manner, and again received the same punishment. He had no constitutional disease from these sores."

Can you imagine this woman the subject of disease all this time? Impossible. Doubtless we are occasionally imposed upon by disingenuous persons, who, having incautiously committed themselves to falsehood, in order to conceal one fault (with which, by the by, we, as medical men, have no concern), maintain it with a pertinacity dictated equally by knavery and folly; but this is by no means invariable, and, I believe, not even common. I find that good sense prevails in the majority of instances; and therefore I would never enter on the inquiry into such cases, with a dogged incredulity, receiving only such statements as suit our doctrines. I am more prone to doubt the doctrine, than throw a shade of doubt on the word of an apparently honest man, upon the exercise of whose honesty may possibly depend his welfare in future life.

Again, as regards the character of chancre, first described by Mr. Hunter, I have already stated that it is greatly at variance with a very large proportion of the venereal sores seen at the present day. You will see sores progressing through their various stages, without the presence even of tumefaction; some, again, attended by partial tumefaction, or even thickening, occurring late in their progress; while others, though rarely, are attended by positive thickening from the commencement, in which the ulcerative action is merely subsidiary and not primary.

These characters, however, are not invariable; they are not always clearly marked in private practice, and still less so in that of a public hospital; and after all, they form but general rules, which, though highly valuable, have many exceptions, owing probably to the blending or modification of the various forms of poison, or to peculiarities which are beyond our ken.

Before I conclude these observations, let me state to you what I understand by a venereal sore. Its definition holds no relation to its progress, and still less, were it possible, to its mode of cure. The definition Mr. Hunter and the surgeons of his day would have given is, a disease obtained by sexual intercourse, requiring mercury for its cure. Half a century, and their experience, have given us some insight into this subject; and this doctrine is, happily for society, now acknowledged to be fallacious. By a venereal sore or

venereal disease, I understand any disease indicating the presence of a poison obtained by sexual intercourse, or communicated by contact with an infected person.

Common primary Venereal Sore—the Venerola Vulgaris of Evans.

The common venereal sore appears from three to five days after connexion, appearing in the form of a pustule, preceded by itching. I shall employ the name given by Mr. Evans. Its progress is first destructive, and then reparative. It usually runs its course with great regularity, unless diverted by maltreatment, dissipation, or by depraved constitution.

It is purely and entirely a local sore, pursuing its career, when unmolested, till it accomplishes its own crisis, *producing no secondary eruptive affection whatever.*

In private practice you may occasionally meet with it in its first or pustular stage; in hospital practice, rarely or never. The pustule bursts, and its place is occupied by a small incrustation formed by the secretion, which, on separating, exposes an ulcer. This occupies from three to four days, when the ulcerative stage commences, at an early date of which our attention is first directed to the sore. Its characters are yet but imperfectly marked; but we can readily ascertain that it is destitute of thickening, by pressing it between the finger and thumb. Its form is generally circular, but that is no criterion. It is cup-shaped, and of a dirty brown or yellow colour, moist, secreting a puriform ichor.

This is the destructive or ulcerative stage, through which it progresses variably, from the tenth to the twentieth day, though I have known it to extend during a period of four months. It is during this stage that the common venerola exhibits the peculiar characters by which it may be generally known—viz. *that its edge rises above the surrounding surface, in the form of a moderately well-defined ring, having, as Mr. Evans says, the appearance but not the reality of induration.* If the sore progresses favourably, the destructive stage ceases from about the fifteenth to the eighteenth day; granulations form at the bottom, which frequently rise above the level of the surrounding skin, or even of the edge of the sore, presenting the appearance of a fungus, and constituting the second, reparative, or granular stage. The granulations are now absorbed, and sinking below the surrounding level, the skin heals over them. This constitutes the third stage, or that of cicatrization.

Although the description given by Mr. Evans of the common venerolic sore, is excellent, yet I am inclined to think he

has coloured it too highly. As far as I have observed, I do not think the elevated character so invariable an attendant upon it as to warrant the second term be applied to it, of "elevated ulcer;" unless, indeed, the name apply to the edge alone, which is much more uniformly raised around the surrounding level. This character, however, as Mr. E. has observed, depends greatly on position. The texture must be loose, and the surface void of pressure from contiguous surfaces.

Thus on the free edge of the prepuce, on its external surface, or on that of the penis generally, on the scrotum or thigh, the characters will be more distinctly marked, and the granulations will be more elevated than on the glans or inner preputial surface. Between the two latter, however, there is a marked difference; the sore on the glans being almost destitute of the elevated character.

That this form of reparative action is due to the structure of the part, may almost be inferred from the appearance of a sore involving at the same time the glans, fossa, and prepuce; which is elevated on the prepuce, ragged on the fossa, and excavated on the glans.

The poison of this sore is probably identical with that of gonorrhœa; the two diseases having many symptoms in common. 1st. Venerolæ are often the attendants on the latter stages of gonorrhœa, where they appear in the form of a crop of small ulcers on the margin of the prepuce or on its inner side, appearing not unlike a growth of soft warts. 2dly. It appears about the same date after intercourse, and pursues its career in about the same period. 3dly. And by far the most important feature of resemblance the two diseases present, is, *that they both exhaust their morbid actions, and reach their own crisis and cure, without the aid of positive treatment of any kind, and are followed, as regards gonorrhœa, rarely or never, and as regards the common venerola, positively never by secondary disease.* Mr. Abernethy was familiar with this sore, but that he was trammelled by the high authority of his idol, Mr. Hunter, there can be no doubt; and hence the greater merit of his essay on this subject. He states, that "a form of sore of the size of the finger-nail, that throws out new flesh rising above the surrounding skin, from which he never knew an example of secondary symptoms."

Do not, however, suppose that this description is applicable to every form of common venerola, the shades of difference between which are both great and numerous; for, as Mr. Wallace justly observes, "it is the progress and whole phenomena alone that can demonstrate its nature."

There is no disease that resembles it in the aggregate of its stages."

This variety is found to exist in a far greater degree in hospital, than in private practice—due, perhaps, to constitution, habits of intemperance, want of cleanliness, and to the early and injudicious resort to remedies recommended by incompetent and uneducated practitioners; among the foremost of which stands mercury.

The glans penis does not appear the soil on which the venerola flourishes in full vigour. It is cramped in its growth without being hastened in its progress, rarely acquiring so large a size as on the prepuce, penis, or scrotum; is more excavated throughout, and appears destitute of that reparative energy essential to the formation of the granular stage; and it always terminates by a loss of substance, in the form of a pock-like depression. Still, on the glans, it often attains a very considerable size. The same form of ulcer attacks the orifice of the urethra, where it is characterized by more than its usual degree of tumefaction, not amounting, however, to hardness, by more pain, and by a greater tendency to the formation of bubo.

Throughout the whole career of this common venerola, "the primary syphilis" of Mr. Wallace, there is found no trace of thickening, hardness, or induration. It may be occasionally attended by more or less tumefaction or soft thickening; but this is not common. Do not be misled on this point. We all understand what is meant by thickening, and on this head, I say, examine for yourselves.

With the exception of the indurated sore (I will not say the Hunterian sore, for I really do not know it, but I mean the hard syphilitic chancre)—there is no ulcer that usually pursues its course more steadily, when unmolested by interference, or diverted from its course by what we call treatment.

Bubo is an occasional, but by no means a frequent attendant on the common venerola; and it is worthy of observation, that the liability to bubo holds a relation, not so much to the activity of the sore, as to the constitutional health of the affected person. I need, then, hardly state, that this glandular enlargement of the groin is not the product of a poison absorbed into the circulation, but arises from what Mr. Hunter called "sympathy;" in reality, irritated absorbents, the result of common, not of specific irritation.

This bubo does not exist in the form of an enlargement of a single gland (a condition that characterizes another form of disease), but of gradually increasing tumefaction of the upper part of the groin,

extending towards the ilium, from two to three inches in length, and of half the breadth; a tumefaction that involves not glandular texture merely, but a large proportion of cellular tissue, giving it the aspect of a slow phlegmon. It does not ordinarily suppurate, but subsides with the disease, unless the circulation have been positively and considerably reduced by treatment; under which circumstances, it may either remain in an unaltered state for several weeks, or terminate in slow and partial suppuration. These observations will apply precisely to the bubo of gonorrhœa, with which, as far as I have observed, it is identical in all its characters.

Treatment.—The treatment of venerola is most simple. The sore requires cleanliness, protection from violence, and moderate attention to the general functions of the system during the ulcerative stage. The local applications should be mild and unstimulating. Common spermaceti dressing is the best. If the sore be within the prepuce, linen may be substituted for lint, that its pressure may not cause irritation. It should be changed about three times in twenty-four hours, the sore being as frequently washed with warm water. All stimulating applications, whether black wash, zinc, copper, or other descriptions of ointment, should be carefully eschewed, being not merely unnecessary, but positively objectionable. Mr. Evans recommends the application of a weak solution of acetate of lead, and poultices, to sores on the outside of the penis or scrotum; in the latter recommendation I fully concur, inasmuch as a poultice is a soft, moist, and innocuous remedy, which protects the sore from external injury or violence. Should the granulations in the later stage rise considerably above the surrounding level, they may be reduced by the application of sulphate of copper, or of a solution of five grains of nitrate of silver to an ounce of water; but either of these remedies should be resorted to, and applied with care, their application being made as lightly as possible. The constitutional treatment is also abstinent. A mild aperient, followed by small inoffensive doses of antimony, if the sore be attended by heat of skin, and constipated bowels, is all, or nearly all, that is required. If unattended by these infrequent concomitants, I have been in the habit, for some years past, of treating such cases with bread-pill night and morning, and I am acquainted with no form of medicine which, as applied to the case before us, is both more efficient, and less objectionable.

Some years since, I was in consultation with an eminent surgeon on a case of venerola occurring in a hospital patient, to which my attention was directed, as to

a case of the true Hunterian chancre; he knowing that my interest had been excited by this subject. I smiled on seeing the "true Hunterian," and merely said, in the absence of the man, that I would, as a joke, lay him a wager that I would tell him, within a few days, how long the sore had existed, at what length of time it appeared after connexion, and, moreover, that I would undertake to cure the disease without the use of any description of medicine whatever; pledging myself, too, that no secondary eruption of any kind should follow the healing of the sore. All this I performed to the letter; and this feat, great as it may appear, requires no knowledge that a little common observation may not afford, in a comparatively short period of time.

This form of venereal sore requires watching, more especially in some depraved states of health; but you must be content to be a quiet inofficious looker-on—probably for weeks. It is always better to withhold your opinion of a case on a first visit, till you see the character of the sore more fully developed. On the second and third, you find the sore extending, and it both will and ought to extend; nor will it cease till it probably attain the size of a tamarind stone, or even something larger. You cannot arrest the ulcerative action but by one mode, and that I think objectionable. Stimulants will not arrest it; nor will mercury. Whatever be the change effected by tampering with the sore in the ulcerative stage, must be superadded to the allotted time for its cure.

The progress of the sore may be interrupted merely, but entirely arrested, by escharotics, provided they be applied early in the ulcerative stage. This plan of treatment is adopted and recommended by Mr. Wallace, of Dublin, who resorts to it very generally, as the means of destroying a surface which seems to have the power of contaminating for a limited period contiguous parts. It is obvious, therefore, that it is applicable only to the first stage of ulceration; in which, if at all, it must be applied freely. Mr. W. employs the nitrate of silver, which should be rubbed carefully on every part of the ulcerated surface.

Instead of the nitrate of silver, I prefer nitric acid diluted with an equal quantity of water, which has this advantage, that being applied to a small surface, it diffuses itself immediately over the whole. This practice is applicable only to a small or early sore, and not to one advanced; for if resorted to in an advanced stage of ulceration, it will often prolong the evil it is intended to arrest. It is a form of treatment which you may resort to in cases of emergency, where time is especially valu-

able. For example—a gentleman is leaving town on an excursion of pleasure, which it is impossible to postpone (matters of business are not generally so imperative); or he may be engaged to be married on a particular day—for these are emergencies, gentlemen, with which we have occasionally to contend. Here you had better resort to the more direct line of cure, which is rarely followed by evil consequences, provided, as I have before stated, the ulcerative stage be not advanced.

As a general rule, there is no necessity for the administration of mercury, in any form or quantity. At the same time you need not forswear its use. In moderate quantities, it is inoffensive and unobjectionable, and may contribute to the healthy progress of the sore. There is a phrase almost universally applied to these minor doses of mercury, which I confess I do not understand—I mean the term "alterative doses." It appears to me that if the term alterative be applicable to minor and limited doses, *à fortiori*, it must be still more applicable to large. The object and aim in the administration of all physic is "alterative," and why may we not have local as well as constitutional "alteratives?"

It is not to the dose that I object, but to the name. You will often puzzle an unthinking man, if you ask what he means by the term "alterative." He will generally tell you that by it the secretions are altered. If you venture to ask what he means by "the secretions," he will answer, and perhaps wisely, that he does not altogether know, but that the medicine does the patient good, and that he strongly recommends persistence in the use of it. This is honest and sensible, and I confess I am often of this gentleman's opinion, fancying, as I do, that we are not always quite so knowing on these and various similar matters as we imagine. However, to the point. Five grains of blue pill to an ordinary patient, not the subject of mercurial idiosyncrasy, may accelerate the cure, when given each or alternate nights; but it should not be used continuously for more than a few days. There is no advantage in what is called "touching the gums;" but generally a great disadvantage both to the sore and to the health. As regards my own practice, I far more frequently abstain from the use of mercury altogether, a very large proportion of the cases I have treated having recovered without the administration of a single grain. I adopt this treatment from no apprehension of the evil consequences of mercury moderately applied, but from the fullest conviction that in the majority of cases it is uncalled for.

When the *fossa glandis* is the seat of ve-

nerolic disease, the sore often looks ragged, and burrows under the skin; but this condition does not warrant any deviation from the simple principle of treatment I have before enjoined. If situated in the neighbourhood of the frænum, that band is destroyed by the ulcerative process, and as of course not reproduced.

Mr. Wallace—to whose work I especially refer, because he has fairly met and discussed several important considerations, both pathological and curative, connected with the venereal disease—recommends the resort to mercurial treatment after the destruction of the sore by caustic, and the establishment by its agency of the action of reparation—that is to say, he is not content with the destruction of the sore, by converting morbid into healthy actions (his own reasoning, observe), but he would strike a second death-blow to the disease, already defunct, lest it should not be quite dead, and should quicken into life. Mr. W. says, “the object is two-fold—to hasten the process of healing, and to diminish the chance of secondary symptoms.” But if his reasoning be correct, there ought to be no chance of secondary symptoms, even supposing the sore be competent to their production, the action of the caustic being that which reduces the ulcer to the condition of a common sore, and what more can be required? Mr. W. considers that he avoids the granular stage, and accelerates cicatrization. First, I would observe, it is an unworthy enemy to combat with so potent a weapon, and that the remedy is infinitely more objectionable than this fraction of a disease, the expense of which to the constitution amounts to nothing; and 2d, that from my own experience of the sore under consideration, I will venture, in opposition to the deservedly high reputation of Mr. W., to affirm that mercury can afford the only possible chance of secondary symptoms that the case will admit of. Either the poison is destroyed, or it is not. If not, the caustic is incompetent to its reputed ends; and, if destroyed, the mercury is superfluous. Let us reserve the use of mercury to cases in which it is indispensable. This disease you may be assured will derive no advantage from its application, either local or general. Its local administration is most offensive to an ulcerated surface, and I will pledge my professional reputation that it is not the remedy for this description of sore. I do not say that the sore will not heal under mercurial treatment; but I do affirm, with confidence, that both time and health will be economized by an almost total abstinence from it.

There are modifications of the common venerola to which I have before alluded,

characterized by less excavation and by considerable induration, which have been described by Mr. Evans under the appellation of *superficialis* and *indurata*—two forms of disease acquiring their peculiar characters from that of the constitution of the person possessing them. The first is an active sore, destitute either of the torpid action of the common venerola in its early stage, or of its reparatory disposition in the second, attended with more than ordinary constitutional disturbance, and greater local irritation. Here the constitution must be treated, and not the sore. The means are antiphlogistic. Purgatives, followed by antimonials, in the form of a solution of two grains of tartarized antimony to a quart of lemonade, of which an ounce or a small wine-glassful may be taken about every half hour. If taken in excess, its effects will prove emetic. Should nausea result, the intervals may be extended to an hour, by which means we obtain a copious purgation, and that depressing influence on the circulation which this form of medicine alone can produce.

The indurated venerola is a rare form of disease, which, as its name denotes, is attended by thickening not very dissimilar to that of the indurated chancre of Mr. Carmichael, to which it is, as I believe, related, or rather it exists as a link in the chain, connecting venereal disease with the true syphilitic chancre; distinct, however, from the latter, inasmuch as it occurs early after connexion, and may, like the last disease, be the product of gonorrhœal matter. Mr. Evans describes it as one indistinctly marked, exuding a fluid from a surface of a healthy red colour, and may be confounded with an excoriation, having sooner or later a base of a cartilaginous hardness, unless the sore be seated on the glans. It is not excavated unless it burrow underneath the skin of the penis.

Mr. Abernethy also describes this sore “as a species of chancre, in which the disposition to ulcerate is less than that to indurate, so that the ulcerated surface may heal and leave a knob.” The chief interest attached to this sore arises from its great propensity to slough. It is not the product of a specific virus, and may arise independent of sexual intercourse.

There are two morbid actions incidental to venereal sores, requiring extensive modification of the treatment ordinarily employed; they are phagedena and sloughing. The first term is employed adjectively, phagedenic, to designate a peculiar destructive action by which sores extend, either by a rapid ulceration, or by slow gangrenous disorganization, more particularly of the surface, in which the margin

appears, to use the term applied by Mr. Wallace, nibbled, or irregularly broken down in the destructive process. The second indicates a more rapidly disorganizing action which attacks the whole sore, converting it into a gangrenous mass.

Of the first I shall not speak at present, because it is too fruitful a subject to be cursorily introduced here, characterizing, as it does, a large proportion of sores throughout their entire progress. The sloughing action, however, is rather to be deemed an incidental occurrence, and is much more rarely met with.

Any form of venereal sore may be attacked by inflammation of a severe and dangerous character, which may run rapidly into gangrene, involving the sore itself and the surrounding textures. It is not an action inherent in the sore from its earliest appearance, but may be deemed accidental, and dependent on causes often occult, arising during its progress. That it is not a venereal action may be inferred from the following phenomena:—1. It may attack any sore of whatever character, indurated or not. 2. It rarely exhibits itself in the early stages of the disease, during which the poison may be supposed to be in force. 3. Its attacks are directed generally, though not exclusively, on sores within the prepuce, whether on the glans, corona, or inner lining of the prepuce. And 4. It is more generally attendant on constitutions which have been reduced by active depletion, or whose functions have been impaired by excess. This important change is usually ushered in with slight fever, and its concomitants, during which the sore becomes discoloured, assuming a livid red colour, secreting a dark-brown fluid, which discolours the dressing. The prepuce becomes first oedematous, and is withdrawn with difficulty, and then inflames, participating in the change which is progressing within. Phimosis follows with advancing fever, and great local pain, increasing the general symptoms. Immense quantities of a sero-purulent fluid escape from the prepuce, attended with extreme local suffering. Pressure on the glans may generally detect a rapid extension of the sore in the circle of the fossa glandis, the structure of which is broken down into flocculent and fetid sloughs, which escape with the discharge.

The factor is eminently characteristic of this condition, and may be perceived at a considerable distance from the bed. The whole penis sympathizes; inflamed absorbents along the dorsum penis are indicated by a rigid line extending to the pubis, which is eminently painful on pressure, and aggravated by the dependent position of the organ, by which the in-

teguments on the dorsum are rendered tense.

The treatment is essentially antiphlogistic, and that almost without reference to its probable injury to the future health of the individual. The destructive process is so rapid, and the value of the organ so great, that no expense can be deemed exorbitant with which to purchase even temporary relief. If the disease be external, and accessible to local means, even the antiphlogistic treatment must yield to more direct means of arresting the destructive actions of the sore. This may be effected by the free and unsparing application of the undiluted nitric acid, which must be carefully but extensively applied on every part of the gangrenous surface, till the whole is converted into a soft white crust. This may be followed by a full dose of laudanum, and the crisis of the disease is accomplished. When the sloughing action is confined within the phimosed prepuce, and of course inaccessible to local means, as large a quantity of blood must be taken by venesection as the patient will bear, accompanied by the exhibition of full doses of mercury both internally and by inunction, with the view to affect the system specifically as early as possible—not with the intention to kill a poison, but to arrest inflammation, of which the gangrene is the immediate product. Frequent ablution by injection of warm water, or strong decoction of poppy heads, by means of a syringe, should be employed for the purpose of dislodging any disengaged portion of the gangrenous mass that may be separating; and cold water, or a bread and water poultice, as may best suit the fancy or the reasoning of the practitioner, should be applied around the penis.

Probably these means, freely employed, may at once succeed in arresting the progress of the disease: should they not do so, and their failure will be indicated by the recurring pain and protracted fever, the prepuce should be divided to a sufficient extent to permit its retraction beyond the glans. The nitric acid should then be applied according to the directions I have before given, although it has appeared to me that the relief afforded to such sores from their exposure is so great as often to supersede the necessity of applying more than the diluted acid. As a general rule, the sloughing process forms the crisis of the sore, the slough separates, and the sore quickly cicatrizes; but this is not invariable—in some instances, and especially where considerable thickening has preceded the sloughing, as in the true indurated sore, the specific characters of the disease may resume their influence, and pass through their various stages, as

though nothing had happened to disturb them.

The summary of the above is as follows:—

1. That the common venereal sore (venerola) appears within a few days after connexion.

2. That it is ordinarily characterized by its elevated margin in the second stage; the granulations also frequently rising above the surrounding level whenever the sore is situated on an exposed surface.

3. That in its early stages invariably (excepting in the rare form of the indurated venerola) it is destitute of thickening or hardness, which however exists occasionally in the latter stages of protracted sores.

4. That it is followed by no secondary disease whatever.

5. That the action of mercury is unnecessary in the treatment of venerola, inasmuch as the poison exhausts itself early in the progress of the sore, and that when employed, it is incompetent to arrest it*.

REPORT OF

PAROCHIAL LYING-IN CASES DURING THE YEAR 1838.

By JAMES REID, M.D.

Medical Superintendent of the Parochial Infirmary of St. Giles and St. George, Bloomsbury.

To the Editor of the Medical Gazette.

SIR,

I FORWARD the enclosed Annual Report of lying-in cases for insertion in the MEDICAL GAZETTE, should you think that it would interest any of your obstetric readers to compare it with that of 1837, which appeared in its pages last year. The number of cases, though not large in amount, will still perhaps prove of some little value as to its statistical details when added to or compared with others of a similar nature. It is, however, larger I find than the number reported from the lying-in hospitals of Dresden, and some other cities, the annual returns of which are to be found in the German journals.

By comparing the reports of 1837 and 1838, it will at least shew how unsafe it would be to deduce any statistical facts from the results of small numbers, as will be seen in the relative

proportion of sex of the children born, and other details.—I remain, sir,

Your obedient servant,

JAMES REID.

10, Bloomsbury Square,
April 22d, 1839.

330 cases were delivered by the midwives, in which number 9 cases of twins occurred. Total number giving birth to 158 males and 181 females, of which 18 males and 17 females were still-born.

The *greatest number* of births took place in January and May. The *smallest* in October and November.

Of the women delivered, the greatest proportion were between the ages of 25 and 30. There were of the age of 17 and under, 4; between 40 and 45, 18.

Unnatural presentations, complications, or accidents, occurring during or after parturition. Of the above 330 cases,

The breech presented in 8 cases.

Breech and hand in 1

Foot 1

Head and hand 4

Arm 3

Face 4

Head and funis 1

The placenta required manual extraction in 7

Accidental flooding before delivery 1

Hæmorrhage after delivery 7

Convulsions 1

Lingering labour 20

Premature birth 4

Ruptured perineum 1

Turning was required in 3 cases.

The *forceps* 3

Perforation 2

MORTALITY.—In the 330 cases 2 deaths occurred; one from dropsy, the other from pectoral disease and hæmorrhage.

Unusual presentation of the Head and Arm, with Contracted Pelvis.

Saturday, July 14th, 1838.

I was requested by the midwife to visit Ann Drew, æt. 25, who had come into the lying-in ward on the 9th, since which time she had had occasional, though weak pains. A shew took place on the 11th, and an examination was then made, when it was found that the os uteri was only slightly dilated, its

* *Erratum*.—In last lecture, the two lines at bottom of c. 2, p. 234, ought to follow last column of opposite page.

lips being very thin. Some soft part was then thought to be presenting.

Pains came on more strongly on Friday, the 13th, continuing through the night, but not with much effect. It was at this time that I first saw her, as the midwife informed me it was a cross-birth.

On examination I found the os uteri enlarged to nearly the size of half-a-crown, the membranes were entire, and through them a hand could be felt, situated towards the sacrum, whilst high up towards the pubes was a harder substance, apparently the head. I visited the patient again in the evening, and found that the membranes were ruptured, although the pains had been but slight. The hand could now be felt distinctly presenting with the head in its natural position. I introduced the fingers of my left hand within the os uteri, and succeeded in pushing up the hand of the infant, and in retaining it there until two or three slight pains caused the head to descend into the space which it had occupied. As in the succeeding pains, which were still very inefficient, the hand could not be discovered on examination, I ordered the patient an opiate draught, expecting that her pains afterwards would become stronger, and that nature would then complete the delivery. The midwife was requested to send for me should any thing particular occur.

At ten o'clock the next morning, I found the head now filling up the cavity of the sacrum, and low down; but I was informed that it had made no advance since three o'clock. A putrid effluvia was very perceptible on entering the ward, denoting the likelihood of the child being decomposed; but still I thought it prudent to use the forceps. On introducing one blade, however, a great quantity of flatus escaped, with putrid fluid; so I withdrew it, and had recourse to the perforator. There was much more difficulty in drawing down the head than I have usually found; and when at length the right ear was discovered, the fingers of the left hand were found lying prone on the cheek, anteriorly to it. Fearing that any continuation of the traction, whilst the arm was in this position, would have the effect of lacerating the perineum during the passage of the elbow, a fillet was passed on to the wrist. Traction was then used by means of the blunt hook,

the fillet being drawn at the same time towards the sacrum, by which means the arm was brought out at its proper side. The head now descended with much more ease, elongated, and with the face to the sacrum.

A considerable time elapsed before the body could be brought down; and this was only effected by fixing the blunt hook under the scapula.

The toes of the right foot were now seen lying supine on the abdomen, a little above the umbilicus, pointing directly upwards. Another fillet was passed round the ankle, and the foot drawn down by giving it a sweeping direction into the hollow of the sacrum. The left leg descended easily. The umbilical cord was round both legs, in the direction of a figure of 8. The infant was decomposed, and the placenta very much so.

On examination afterwards a slight projection of the sacro-vertebral promontory was found to exist; and owing to this, combined with the unusual position of the child, the inefficient pains which the woman had throughout her labour, were unable alone to effect its descent.

Hæmorrhage and Diseased Lungs.

April 29th.—Jane Bristow, æt. 21, a woman of colour, of very small stature, and much deformed, was admitted into the lying-in ward, and delivered of her first child (which was in a putrid state), without much difficulty, on the 28th of April, having previously suffered, it appears, from some affection of the chest. The day after her confinement her cough became very troublesome; the respiration laborious; pulse 100, but not strong; rigors, headache, and thirst. She complained of much pain in the chest and abdomen. As flooding had come on to some extent, and had much reduced her, it was not judged advisable to bleed her from the arm, but twelve leeches were applied to the chest, followed by a blister and a calomel and opium pill given every six hours. She sank gradually, however, and died on May 1st.

On a post-mortem examination, great lateral curvature of the spine was found, bending towards the right side, and touching the ribs, there being very little trace of the right lung remaining. The left lung was much diseased, and bloody serum was found in the pericar-

dium. The pelvis was well formed; her legs measured only twenty-five inches in length.

Impaction—Use of Crotchet.

May 18th.—Ellen Foy, æt. 38, residing at 3, Smart's Buildings. Labour pains commenced on the 17th, and had continued strongly for upwards of fifteen hours, when I was first called to her. I found the external parts œdematous and much swollen, the internal parts heated, the os uteri well dilated, and the head presenting naturally, but still high up at the brim. No movement of the child had been felt for several hours. As the common forceps were of no use here, I applied the long ones; but after using moderate force for some time, no advance was made, although I compressed the blades together to some extent. The parts were too swollen and heated to leave the woman without further immediate aid, and I therefore determined on using the perforator; after which the child was easily brought down. The woman had borne a live child three years before, after a very tedious labour by the use of the forceps. There was an evident contraction of the sacro-pubic diameter. Crural phlebitis followed delivery, but was subdued by leeching, the use of calomel, opium, &c.

Very small Vaginal Orifice.—Inertia of Uterus. — Twins. — Forceps required to both.

May 27th — Hannah Howard, æt. 29, in her first pregnancy, came in on the 24th, labour pains having commenced on the evening of the 23d. The midwife informed me that she had made an examination at the time, but the orifice of the vagina was so small that she could hardly discover it. She at length did so, but could only distinguish the infant's head through the parietes of the uterus, she not being able to reach the os uteri. Slight pains continued through the 25th, but without producing much effect. I was called in on the 26th to visit the patient, and found the os uteri dilated to the size of half a crown, but its lips so extremely thin that it really required some care to distinguish them from the scalp of the child's head, as they were placed in such close apposition to it. The orifice of the vagina was very small and rigid,

more so than I have ever met with in the adult. As she had had no sleep for many hours, I ordered her ʒss. of vini opii.

The pains continued very weak, and at 2 P.M. the midwife gave ʒss. of secale, which was repeated again in the evening.

27th.—The pains became stronger in the night, and the infant's head had descended tolerably low down by the morning, but no advance had taken place since 3 o'clock. The patient has not felt any movements of the child for many hours.

As the head was now within reach of the forceps, I thought it better to apply them, the action of the uterus continuing still so feeble; but I found much difficulty in introducing the second blade, owing to the small size of the os externum. On adjusting the instrument, however, the child (still-born) was easily extracted.

On making an examination after this, another child was discovered high up, with the head likewise presenting. No pains came on, and the patient was, after a short time, made as comfortable as possible, and obtained some sleep.

28th.—Secale had been given twice during the morning, and the child's head had descended, but apparently without pains, to the same position in which the first had remained. The forceps were now introduced without difficulty, and a full-sized female child extracted, which had been dead two or three days. A fetid discharge accompanied it. The two placentæ, which were somewhat decomposed, came away without assistance, and still without any pain being felt by the patient. The uterus contracted well, and tepid injections brought away much fetid discharge. The woman did very well afterwards.

In this case, the remarkably small vaginal orifice proved no difficulty to the exit of the children, as it expanded easily. The patient throughout suffered little from pain, as the uterine action seemed almost arrested by the distension of that organ; each child being as large as single infants generally are. No bad symptom followed this inertia, as there was not even any sign of hæmorrhage.

Convulsions.

The following is one of the worst

cases of this description which I have ever seen survive :—

June 17th.—Mary Fenning, æt. 22, residing at 4, Russell Place, Little Coram Street, a patient of the Bloomsbury Lying-in Charity, had complained of pain in the head, with great uneasiness and restlessness, for some days past.

I was called up to visit her at 4 A.M. by the midwife, and found the patient, a young woman apparently of active temperament, dark complexion, and of very small stature, struggling most violently, and throwing herself about in the bed, notwithstanding the exertions of two strong women to restrain her. The eyes were open, and the teeth firmly clenched. Examination per vaginam proved that the os uteri was undilated, and the slightest touch on these parts caused great irritability.

I immediately abstracted 30 oz. of blood from the arm, though with difficulty, owing to her struggles; this rendered her much more tranquil, though it was not attended by any return of consciousness. Her hair, which was very thick and long, was now cut off, and the head kept covered by cold cloths. At eight o'clock about 15 oz. of blood were again abstracted, as she was still in a state of stupor; two drops of croton oil were placed on her tongue, and a blister applied to the nape of the neck. Convulsions still continued with great force.

At 3 P.M. the os uteri was not dilated in the least, the convulsions still remaining, though not so strongly. About 7 P.M. labour pains came on suddenly, and with great force, and the infant was very speedily expelled, the placenta following immediately after. A terrific convulsion of great strength and duration accompanied this action of the uterus, and immediate death seemed almost certain. Coma continued, but fortunately no other convulsion followed.

Cold applications to the head were continued, and 5 grs. of Calomel with ℥j. of the Pulv. Jalap. Comp. were administered immediately it was possible to do so.

The next morning she had recovered her consciousness sufficiently to understand the questions put to her, but was almost unable to speak through the day. Aperients had their proper effect, and on the 19th she was able to converse, complaining of pain in her head and back. The tongue, which had been se-

verely bitten during the convulsions, now occasioned her much discomfort. All her troubles left her in the course of two days, and at the end of the week she was out of bed.

Dr. Ramsbotham has remarked, in his valuable Practical Observations, that he had witnessed the occurrence of several cases of convulsions during warm weather, when the clouds were charged with electric fluid. I may mention that this case occurred on a day which was remarkable for this precise state of the atmosphere.

The case of dropsy which proved fatal has already appeared in the journals, in the reports of the Westminster Medical Society. I find that Dr. Haighton mentions a similar case, in which the abdominal collection of water escaped through the uterus by means of the Fallopian tubes.

The case of ruptured perinæum was unfortunately complicated with hour-glass contraction of the uterus and retained placenta, which required that the hand should be passed up to extricate the latter, notwithstanding the accident.

In the second case, requiring perforation of the child's head, owing to impaction, I find that I had to perform the same operation three or four years since; but that she had brought forth a living child in the interim, by the aid of the forceps.

ON THE PROPOSED RENOVATION OF THE VACCINE VIRUS.

To the Editor of the Medical Gazette.

SIR,

THOSE who are officially employed in the practice of vaccination, are, of all others, the most interested in the vital questions now agitated, concerning the degree of permanence of the protection which it affords, and the degeneracy in the needful activity of the virus, which it is now so much the custom to attribute to it. These are totally distinct questions, and not of necessity connected with each other. I have not been inattentive to the very meritorious exertions on this subject, by a gentleman of Mr. Estlin's high character for professional attainments, in his endeavours to substitute for the virus in present use one more directly derived from the cow,

and to which, from its increased activity, he is disposed to attribute a higher degree of protective power.

The fact, however, of such degeneration of the virus I consider as still undecided, and as such, it is open to the testimony of all who have been in the habit of using it for a sufficient length of time to enable them to watch its progress from year to year, and to institute a fair comparison.

In a letter on this subject, which you did me the favour to insert in the *MEDICAL GAZETTE*, April 2d, 1836, which was a sequel to another in Feb. 1834, I shewed, that in Dr. Jenner's very first experiments on cow-pox, as soon as the virus had passed by inoculation through a single human subject, "it was immediately brought down to a state, hardly, if at all, different to that in which we now see it, though it must now, on a fair computation, have passed through a thousand" (*not a million!*) "successive subjects, since each transmission occupies no more than a week in regularly sustained practice." I also stated that the unanswerable proof of some constitutional affection is still shewn by Bryce's test of revaccination during the early progress of the first vesicles. Having had no personal experience whatever of the new virus which Mr. Estlin has taken such laudable pains to introduce, I am unable to add my testimony to its efficacy; but being one of those surgeons to the National Vaccine Establishment who returned an opinion of the hitherto unaltered appearance of the effect following ordinary vaccine inoculation, I think myself entitled, without making a parade of thirty years uninterrupted practice, to state my reasons for this opinion, as the experience of a single individual. It is only by collecting and comparing such statements that any correct general inference can be drawn.

I really cannot find that the disorder, as now produced, has at all habitually lost any of its essential symptoms, or has become so uniformly milder as to furnish a probable mode of accounting for the numerous failures in its protective power that have lately been noticed. I use the qualifying terms *habitually* and *uniformly*, because at all times there have occurred, here and there mingled with the cases of statute regularity, some deviation which were considerable enough to be noted and registered at

the time. Most of these relate to the period at which the areola makes its appearance, that most essential character of effective vaccination, which is usually fairly established by the eighth day in the hardened base and inflamed ring round the vesicle, and increases in extent and integrity for about two days longer before it declines. At the present day, as has always been the case, I sometimes find the progress of the areola hastened, more rarely retarded, but not deviating more from a standard period than occurs in the other exanthema, and especially in small-pox, and therefore justifying the opinion of average security. In the paper which I have alluded to (*MED. GAZ.*, Feb. 1826) I have described these varieties more fully.

That these occasional varieties depend commonly on the state of the recipient of the virus, rather than on that of the virus itself, is not a matter of mere conjecture, but of easy proof. In inoculating half a dozen patients at the same time, and from the same source, we shall find, a week after, in one or two of them, perhaps, that clear pearl-like vesicle, rising perpendicularly from the surrounding skin, flat at the top from being as it were tucked in at the centre, and turgid with a clear watery lymph, such as Mr. Estlin has so well described in his last letter. The child that exhibits it has probably a plump fair skin, quite free from any local irritation in any part of the body. Another patient will exhibit nearly the same appearance of vesicle, but already red and hard at the base, from the more rapid progress of the areola. In the next, the child being in active dentition, and the skin here and there rough and pimply, the vesicle, though having the characteristic form of prominence at the edges, and depression in the middle, will lie deeper buried in the integuments; the fluid contents abundant, but not so easily obtained by mere puncture; and though still limpid, not quite colourless, and the areola pretty far advanced; the more so, perhaps, from the rubbing against the sleeve, which the child employs to soothe some degree of itching, which does not take place in the former case. Is the security in this case equal to the other? I should say it probably is, because, in the first place, the virus introduced was quite unexceptionable; and because, though the coming on of the areola is somewhat

anticipated, it continues quite as late and more extensive than in the milder form; and especially because Bryce's test is also equally available.

But it is not the excess but the want of local irritation that appears to be frequently complained of. Besides the delay in the progress of the vesicle occasioned by the interference of the contagion of other diseases which I have noticed in my former papers, I believe the chill of very severe weather and the exhaustion of diarrhœa often retard, though seldom entirely prevent, the vaccine disorder. A pale, flabby, squallid, early-weaned child is sometimes brought, in whom you may predict, with certainty, that the vesicles will be slow in advancing, scanty in lymph, lying for many days loose in the skin, and slowly creeping on to a regular but faint areola. Is this sufficient for average security? With some hesitation, I should say that probably it is, for the disorder has gone through all its stages, and in two or three such cases in which I have tried Bryce's test it has answered perfectly well. I therefore must conclude this part of the subject by repeating my opinion, as far as personal observation extends, that vaccination with the virus now in use is, both in its regular form and in its varieties, in no perceptible degree different from that which we employed in the earlier days of this still invaluable discovery.

Though not a member of the Vaccine Board, I think I may be allowed some observations on the censures which Mr. Estlin has heaped upon that body with no unsparing hand, and especially on the notice he has thought proper to take of the obvious and somewhat absurd mistake in the last Report, of the word *million* for *thousand*. How, and by whom the Reports are drawn up, I do not exactly know; but to suppose that any persons of common sense would seriously attempt to give to the practice of the establishment an antiquity which a moment's calculation could carry back far beyond the creation of the world, and to insinuate that this desperate attempt was a *pious fraud* to enhance its importance, is to stretch an unfriendly feeling to a violation of candour which I most sincerely regret.

I must also think that the Board have shewn a sound discretion in declining to become the medium by which the virus introduced by Mr. Estlin should

be generally circulated; unless they were prepared at the same time to adopt it, to the exclusion of that which they usually transmit. If the new virus continues to maintain its asserted superiority through several periods of reproduction, there is no doubt but that it will make its way by the zealous exertions of its present friends, and may be brought into general use in less time than perhaps would be imagined. But were the Board to give out that they possessed, and could transmit, two varieties of vaccine virus, one of them considered by many as far preferable to the other, what would the public conclude, but that they dealt in a better and a worse article; one genuine, and one almost spurious; one worn out, the other in its prime; one for choice, the other for ordinary purposes? Instead of combining to the same end, the success of either would tend to shake the confidence in the other. If, too, any vexatious failure should follow the use of the renovated virus (the occurrence is possible) how easy to insinuate *bad faith* in the distributor; how difficult to disprove the accusation!

Two more subjects of censure Mr. E. has brought against the Board. One is an indifference to the statistics of vaccination, the other a neglect in making known to the public the legal penalties and prohibitions against wilfully spreading small-pox contagion. The latter is not entirely correct; since, in every one of their printed wrappers, it is expressly stated, that "persons exposing patients affected with small-pox, and medical practitioners and others who inoculate with that disease, and concur in such exposure, are liable to a criminal prosecution for the offence;" and a reference is given to two legal decisions on this point. But had it been entirely omitted, I cannot see that much harm would be done, considering the total practical neglect of this prohibitory law; and, moreover, the entire omission of any thing like domestic precautions amongst the houses occupied by the lower classes—the great nursery and hot-bed of variolous contagion. If they could keep effectual guarantee, they would not; and if would, they could not; so that it is needless to discuss the propriety of attempting to enforce it. It is a little amends for a severe small-pox epidemic, that it often frightens to the vaccine

stations those on whom mere persuasion would be thrown away.

With regard to the imputed neglect of the *statistics* of vaccination, I suppose this term chiefly refers to the striking an average of success or failure of protection, total or partial, in a sufficient multitude of cases, by observations spread over the largest number of years that have elapsed between the insertion of the supposed protecting power and its occasional failure. In this country, at least, this object has never been attained, except in a very imperfect and limited degree, and is probably unattainable by any private association, or by a public body who derive from government only the means of existence and facilities of intercourse. The activity and intelligence which direct the practice of the Small-pox Hospital can give, and have given, highly valuable data in cases of failure of vaccination, as to the length of intervening time, the proportionate severity of disease between these and the totally unprotected, and the like; but this does not meet the question, the most important of all, of the numerical value of the average protection from small-pox, afforded to all the vaccinated by Dr. Jenner's discovery.

But if it be still urged upon the Board, "you have for many years been employing practical vaccinators, dispersed over this great metropolis, what is the result of their experience? Let each of them be put upon the scent, and hunt down the facts from which to draw our inferences." First, then, he must turn back in his registers for seven years, (*seven* being universally held as a pivot number for all changes and series, so that already our patients constantly put the question, "Is it not true, sir, that it only holds good for seven years?") Then, as to the number of cases required for a fair average, the larger the better; but less than five hundred would hardly answer any useful purposes; so that, being armed with three times as many names and places of abode, he must endeavour to find out, in the lanes and alleys of this metropolis, where the artisans usually congregate, some clue to five hundred lodgers who were seven years ago living in the indicated places, and their now half-grown boys and girls. In this pursuit he would meet with civility in most places, particularly

from the usual courtesy of the female sex towards the medical profession, and probably would have some active assistance as soon as they were convinced that no sinister end was to be answered. Supposing now, that by long and diligent inquiry he had collected the information which he was seeking—that is to say, the proportion out of his whole number that had been visited with small-pox, mildly, severely, or perhaps fatally, still one great element would be wanting to his calculation, namely, to discover whether the untouched had merely *escaped* small-pox contagion, or had *resisted* it.

In first introducing the practice of vaccination to public notice, the proof-trial was of course for some years the subsequent inoculation of small-pox on the vaccinated individuals. When the permanence and universality of the protecting power was thought to be well established, small-pox test inoculation was abandoned as unnecessary: now, when the protection is found to be less certain, it is abandoned as attended with possible hazard; whereas a second vaccination renews the security without the risk. Our inquirer, therefore, must complete his task by persuading the parents to require, and the young people to submit to a second vaccination, and to give sufficient attendance to verify the effect. Where a royal order can revaccinate an army, or a ukase all the registered serfs of a province, who crouch before the unsleeping eye of power from the cradle to the grave, these useful acts of authority are easily performed, and little liable to error from neglect or wilfulness. I need not say that our title of "National" gives no such authority, scarcely influence, to our own establishment. We must win our way by persuasion, if at all; it is even difficult for us to prevail on many parents to return with their children at the time required for mere inspection of the disorder in its progress, as they are aware they will be called upon to make the slight return for gratuitous service, by affording a supply of the virus by which they themselves have profited. In many, however, a better feeling is found; they admit the reasonableness of the return required of them, and they are not wanting in thankfulness to the surgeon himself, who, if his attendance has extended over many years, after being employed with each successive

child of one goodly family, is often called upon to repeat his good offices to those of a second generation.

The Jennerian discovery, after it had been fairly launched into the world, and before the limitation of its powers had been brought to the proof, certainly suffered some injury by the supposed entire simplicity of the whole subject, which, even in medical practitioners, led to a carelessness in noting the anomalies, if not to a denial of their existence. Its value is still much greater than that of any other remedy for any known disease at all comparable to small-pox in mischief to the human race. A debt of gratitude is therefore owing to those who, like Mr. Estlin, gratuitously devote their time and their abilities to remove defects which cannot be denied, ought not to be underrated, and which still interpose to prevent the full completion of the eminent discoverer's wish, that in time small-pox should be known only by name, and by the records of its ravages.

I remain, sir,
Your obedient servant,
C. R. AIKEN.

Great James Street, Bedford Row,

CASE OF
DISLOCATION OF THE LEFT
FEMUR ON THE PUBES.

To the Editor of the Medical Gazette.
SIR,

JOHN COVERDALE, æt. 43, was employed, on the 13th February, 1839, at a quarry, in Burniston, when about one ton of earth suddenly fell upon his body and right thigh, throwing him upon his back. A second fall of earth immediately succeeded to the first, but striking with great force upon the inside of the left thigh (the right being already fixed), dislodged the femur upon the pubes.

My pupil, Mr. Best, who first saw the patient, immediately discovered the nature of the accident; for there was a very distinct bony prominence on the pubes, a great depression in the usual situation of the great trochanter, the limb everted and separated from its fellow, and about an inch shorter in length. My partner, Mr. Travis, and myself, made arrangements for the patient to be brought to Scarborough, where more efficient attentions could be

secured. On calling a consultation, which was obligingly attended to by Mr. Weddell and Mr. Wilson, we found that no proper apparatus for the reduction existed in the town; that the case was of such extreme rarity as never to have been seen by any of us, either in hospital or private practice, but the course to be pursued was laid down by Sir A. Cooper, in his work on Dislocations, and we felt no difficulty in our operations.

Having first placed our patient as upright as we could, on a firm bed, he was bled to 25 oz. As he had only been poorly fed, we did not feel warranted in further depletion. Tartar emetic was then given in divided doses, to the amount of six grains, but neither syncope nor sickness supervened. He was now laid upon his right side, the left knee bent, and given in charge to an assistant, while a strong towel, passed within the groin to fix the pelvis, was attached to an iron bar, beyond and just before his head. For want of proper pullies, we had recourse to the rather unwieldy ones used in ships, having a single purchase with two single blocks. These were attached to a staple in the floor. A good deal of time was lost at first in adjusting the apparatus to the knee, so as to give a sufficient firmness of attachment without acting too tightly and injuriously on the skin.

Extension was now made with considerable force downwards and backwards for about ten minutes, when the bandage at the knee gave way. Mr. Weddell then reapplied the cords very tight, and extension was renewed in the same direction. After persevering for about ten minutes or a quarter of an hour without any apparent success, the head of the bone at length seemed to have moved. During this evident relaxation of the muscles I directed the extension to be desisted from, and lifting up the thigh with a towel placed round it and the back of my neck, Mr. Weddell gently turned the knee inwards, making a lever of the limb. The head of the bone returned to its place with a slight snap. The fever after the accident was scarcely perceptible. A little sickness and griping supervened, probably from the tartar emetic; and an aperient was all that was required during the subsequent treatment. The patient was kept in bed three days, when he got up and

walked across the room. I saw him about seven weeks after, when I found him walking very well, able to rotate one limb as well as the other, and only complaining of a little weakness in his knee. The time which elapsed from the occurrence of the accident to the reduction was about seven or eight hours.

In conclusion, I beg to acknowledge myself much indebted to the ready and efficient co-operation of my medical brethren on this interesting occasion. A similar case occurred in the same village in the year 1756, in the practice of Mr. Travis's father, which is recorded in page 99 of the second volume of "Medical Observations and Inquiries." This was reduced without pullies.

I am, sir,
Your obedient servant,
JOHN DUNN.

Scarborough, April 25, 1839.

SELF-INFLICTED WOUNDS.

To the Editor of the Medical Gazette.

SIR,

If the following is worthy of a place in your valuable journal it is much at your service.

Your obedient servant,
WILLIAM TARLETON.

Birmingham, April 24th, 1839.

Early in the morning of the 13th of December, 1835, I was sent for to see Mr. —, æt. 29, residing at Lee Crescent. His sister informed me, on her hearing a noise in the kitchen she went down stairs, and discovered her brother in his night shirt streaming with blood from his head, with a cleaver by his side. When I first saw him (about one hour after the occurrence), he was extremely pale from loss of blood, sitting in a chair, and sensible enough to be aware of my presence. On examining his head I found upwards of thirty cuts on the posterior portion of the parietal, and superior portion of the occipital bones on the right side, in a horizontal direction from behind forwards, of different lengths and depths, some mere flesh-wounds, the longest of which measured four inches; others extending quite through the bone, so as to completely cut out a piece nearly one inch long and half an inch broad, cut transversely about the middle of the lambdoidal suture, through which portions of brain

escaped. All the wounds, I have not the least doubt, were inflicted by himself. He must have held the cleaver overhanded. It is not probable that he could have been taken out of bed and forced down stairs without disturbing the family, on whom no suspicion could rest, and all the outer doors were examined and found fastened. He survived four days, part of which time he was sensible, and acknowledged having done it himself. He had been removed from London the day previous, in consequence of being insane.

The object of this communication is to record fact, that such an important and extensive wound could be self-inflicted. I shall merely add, that he was attended by Mr. Bracey (who lives in the neighbourhood) and myself; that a coroner's inquest was held, and a verdict given according to the opinion expressed above.

SKETCHES OF MEDICINE IN PARIS.

NO. II. SKIN DOCTORS.—ALIBERT.

Who has not heard of Alibert, the great scabrographer of Europe? It was on a fine July morning, now some years ago, that, under an avenue of limes in the great court of the Hôpital St.-Louis, with two hospital sheets for a "tentorium cerebello superextensum," and mounted on a temporary platform—a theatre for himself and his disciples—I was first introduced to this renowned and meritorious dermatologist. Before him, on his desk, lay rolls of portraits of different unsightly acquaintances, and pegged upon the trees, like linen hung to dry—a large assemblage of monstrous productions executed by the painter to the hospital. It was, on the whole, a bad preparation for a *déjeuner à la fourchette*.

Here you might study, *not* at your ease, the various modes of mischief entailed by syphilis upon the race of mortals. Look at that poor negro's face, which *first* challenges notice from its colour; a devastating ulcer of Paphian origin has made one month of the whole nether face, which to describe further were nauseous. Six other faces are stamped with equally impressive texts, warning you to beware that "idem est dissimili semper in ore Deus." A little further off, see that huge tumor which

thrusts forwards a sightless eyeball, destined soon to occupy the whole orbit, and extending in an opposite direction towards the brain. The pinched chin and straw-coloured cheek render the fatal word cancer written below unnecessary. More frightful still in its outward manifestation, is, behold! polypus. Those raised and blood-shot eyeballs seem to glare in phrenzied agony. On another tree or branch a hugely-swelled parotid swamps the whole face in its ceaseless growth. Simple hare-lip is not pretty, but what would you take to approach within a yard of those lips fissured with green gangrene? Yet, even here, the painter occasionally intersperses with these horrors a dash of something less revolting. See that self-satisfied youth, with his *mentagra*; and those females tricked out to exhibit the attractions of acne. But hark to the hum of voices! the morning's instruction is about to commence. The pupils in hundreds flock round the benches, inkstands are uncorked, and pens preparing to take notes; others examine, ere it ascends the platform, each unknown malady, come to claim a name, and to obtain, if possible, an asylum. But I must introduce you first to Alibert himself. You see, at a glance, what kind of a person Alibert is: a frank expansive countenance that there is no mistaking; where shrewdness is united to benevolence, and discernment apparently joined to great simplicity and *bonhomie*; you hear him called by his pupils, "le bon père Alibert." Well, Alibert is good natured, and so far benevolent; he is discerning, and uncommonly shrewd; but as to his simplicity, its all affected—the *ars, celare artem*. As a lecturer, there is none that we would listen to with greater pleasure, for he is eminently conversational; which advantage, however, makes him, they say, a lecturer in conversation; when, as every body wishes to say something, it is by no means so popular an endowment.

... "Porrigo," thus abruptly would he open his subject, "vilain mot qui sort de la basse latinité du moyen âge, was introduced, together with the foul disease which it designates, by the Crusades. Now, I dare say, gentlemen, that many of you who hear me imagine that the age of chivalry was, if not a golden, at least a very polite and cleanly age, il n'en était pas ainsi; au contraire, it might almost, I think, be

affirmed that the chiefest of the trials to which that chivalry was exposed was the having so many unsightly cutaneous disorders to brave in Palestine; not only the reigning diseases of the country, but such as were soon produced by thirst, vigil, famine, and dirty linen; things, gentlemen, of which Tasso never dreamed, but which the historian of disease is bound to consider in his attempt to trace disorders to their origin. Gentlemen, I state it unservedly, there can be no doubt that we owe scalled head to the Crusaders!"

On *mentagra*—a subject on which he is particularly fond of descanting—"pour faire en quelque sorte," as he tells his class, "*l'histoire de la barbe*," he made many curious remarks, shewing how accurately he had got up his subject and ransacked history. In Henry the Third's time, in France, razors were rare, and the beard was suffered to grow where it list; the consequence of which was, endemic *mentagra*, which affected almost every man in almost every rank in society. Henri IV. "*le monarque galant, lui-même était grand ami pour la barbe; mais pour une barbe bien réglée, que fit-il? il ordonna ce qui suit*"—which was to destroy the crop of hair under the chin entirely; but, to please the ladies, he sanctioned a thin ring of unclipped hair to adorn the contour of the lower jaw.

Mentagra was not much indebted to the king for these regulations. His successor était encore ami de la barbe, mais il avait ses idées (we all have, gentlemen!) Louis' idea was grand: it was in his reign that the idea of moustache was first conceived; but every thing changes, even to our beards; "les jolies petites moustaches, qui avaient succédées à la barbe rayonnante de Henri IV." gained proselytes, and divided with it the favour of the sex; but moustache lost all its triumphs and sustained a signal overthrow on the accession of Louis VII. This monarch, like Cicero, was no patron of beard, and ordered folk to keep their chins clean. This ordinance made him many enemies; amongst others, his royal consort, who said that it was a shame for a man to shave like a priest, and to go with beardless lip into battle; so he procured a divorce; but many other husbands got into hot water with their wives in consequence of applying hot water to their chins. In the time of the first Crusades

the fashion was still in favour of the long beard, on the proper cultivation of and attention to which much pains were bestowed. Not only was it trimmed daily, and perfumed at night with costly cerates, but a bag was invented to hold it, and every night after the great chevaliers of those days had said their prayers, they bagged their beards in a sort of reticule, similar in shape to that which the monks used to beg alms in, hence called a "bigotine." "So much for the beards of our ancestors! And next, gentlemen, respecting your own. If any of you now hearing me is conscious of having a beard in that situation (under the chin) where it proved so mischievous in Henry the Third's time, which was proscribed by Henri IV., and not revived by any of his successors, let me exhort him to shave it off; and the rather to induce those who may feel reluctant to comply, let me read you the regulations imposed by the Ministre de la Guerre, or those whose duty it is to look martial, and whose wish it is, like your own, to appear gallant." Such was the mode in which Alibert used to carry on his out-of-door lectures, till within a few months of his death. He was a great favourite, and is still respected and talked of with pleasure by many of his old pupils, who prefer, with allowable predilections, the "tempus actum" and its teachers to their own immediate contemporaries.

SKETCH II.—MONSIEUR BIETT.

Monsieur Biett's face, if represented, and it deserves to be represented, would be better in terra-cotta than in marble. To a superficial observer there may appear a certain rugosity of features, which soon wears away in the intelligence and shrewdness which it displays. The droll way he has of enlivening the tedium of the two long hours' visit, and of keeping up his own and his pupils' attention till the last petitioner for sulphur and fumigation is gone, is unique. During assiduous frequentation of his practice, and some participation of his society, we never heard him utter a silly, and seldom an un instructive remark. His conversation is the "sublime of good sense," as St. Marc Girardin says of Voltaire; he seems unambitious of more extensive fame than his pupils can bestow, and cares not if his observations go beyond the walls of the consultation room. Armed as he is with quickness, uncommon sagacity, and

ample experience, he admits the probability, perhaps indiscreet, question, and affects no unattainable precision; nor does he seek, as the manner of some is to say striking things, but looks on quite "au naturel" under his bushy eyebrows. We never heard him use an unkind word to a patient, and many times have seen him confer on them those little attentions—the unbought charities of life; and this we mention the rather that too many medical men in France seem to forget they are dealing with their fellow-creatures, and appear rather to interest themselves in disease as philosophers, than in the unhappy sufferers as men.

We have said enough to interest the reader in M. Biett's moral character, and shall proceed to some specimens of his intellectual—of that sort of quickness and cleverness which we have praised, and which we venture to think will ever add additional charm to the exposition of all kinds of knowledge. Many of the patients who come to ask advice are afflicted with that unsightly malady which, for want of a convenient periphrasis, we are constrained to call by its opprobrious name of "itch." Biett has been familiar with it for many years; but, unlike other intimacies, not to the shaking of hands. Sometimes the querist (as if aware of the Aristotelian ἀπορίωντος) does not name the disease—"Est-ce bien *la* — que j'ai?" making his hands, which he extends complete the interrogatory. Biett answers such questions in an equally droll and delicate manner: "Oui, monsieur, c'est bien *la* —." But as the "Bourgeois gentilhomme" was taught several ways of varying the same sentence, so does the mode of questioning M. Biett on this interesting existence vary almost *ad infinitum*. The following may serve as some of the most usual ways in which it is presented:—"Monsieur, j'ai la gale." To which he replies, having satisfied himself that it is even so, "Oui, monsieur, vous avez la gale." Sometimes the same question is put interrogatively—"Monsieur Biett, ai-je la gale?" A third, shewing his fingers, says, his friends insinuate that he has the itch. "Que j'ai la gale!" "Eh bien, vos amis ont raison. Your friends are quite right in their diagnostic; you have it in perfection." A fourth flings his paws on the table, and requests "M. le Dr. de prononcer un petit mot sur cette maladie." "Am I to name it

for you," asks M. le Docteur.—"I wish you would be so good." "With pleasure—*itch*!"—"Impossible." "Oh, my friend, with me nothing is impossible."—"But, sir, my wife ought to have taken it, for we sleep together." "Ne vous impatientez pas, mon brave, she will take it, I answer for it, in a short time."—"Peste!" "No—*itch*, I said."—"But, sir," rejoins the obstinate man, "I have not even seen a person with the *itch*." "I did not say you had, did I?—besides, sight is not the sense that communicates *itch*." A man winding himself up for an oration receives a check by the simple monosyllable—*gale*. "Monsieur, vous plaisez," says the patient, malgré lui. "Si vous le trouvez plaisant," gravely responds Biett.—"A la bonne heure." "Au contraire," exclaims the indignant accused, as if Biett had given him it. "C'est une infamie, une abomination." He has still, however, one shot to fire before he surrenders—"Voyez, monsieur: look between these fingers, they are free from all eruption." "Insatiable man! must you have it even between your fingers to satisfy you? Wait a week." "Monsieur! I am afraid you will pronounce this to be *itch*," said a fellow in a blouse, rotating a dirty hand round its carpus, just within the focus of Biett's eye. "Vastly like it, indeed."—And when, sir, might I have taken it?" "Why, my friend, it would be difficult to answer that question; perhaps you are not aware that 'la gale' does not inscribe date "sur ses boutons."

It is a mother seeking admission for her boy—she is a smart little brunette. "Do you wish your son to become demoralized, madam?" "Comment, monsieur?"—"Mais, mon Dieu, oui, madame! morals are not taught in the Salle Henri IV.; on entre avec la gale, on sort avec toutes les vices." "Tiens, c'est drôle! pourtant, monsieur, nous voudrions faire entrer le petit bonhomme tout de même!" He was admitted accordingly.

I saw a sturdy fellow on one occasion return his ticket of admission, as the sight of the words did not appear to meet with his approbation. Most men would have been annoyed—Biett lets nothing put him out. "Monsieur," says he, turning solemnly round, and with a certain air of dignity to another whom he had just refused, for want of room—"Monsieur, vous êtes reçu!" as

though he was admitting him into the Institute. "Vous avez tous la gale—You have got the *itch*, every one of you," to a knot of blackguards, who came up for the ceremony of confirmation; "and observe, gentlemen," he continued to his pupils, as the blouses passed in front of the table, "observe, and make a note of it. Not one of these young men, you see, takes off his hat! in obscure cases, and where you have your doubts, look to the head: if the hat is on, that will settle the question at once; in *itch*, the hat is really diagnostic!"—"Encore, la gale!" "No, sir, there you are wrong—*eczema* is my disease; you told me so yourself last week." "Did I? you have a good memory. Well, last week you had *eczema*; there it is—to-day you have the *itch*; there it is—you have now what we call a 'complication', will you recollect that word?" "I'll try to do so," said the twice happy man, and drew down his shirt sleeve!

CASE OF TIC DOULOUREUX*.

To A—B—, Esq.

SIR,

IN reply to the inquiries which have been made at your request, respecting the case of Master Henry Atkins, who derived such singular and permanent benefit from the use of the factitious German mineral waters, I have drawn up the following statement, which, I believe, comprises all the essential circumstances of his sufferings and his cure.

This boy, aged thirteen, had been previously in excellent health, and was so on the 25th March, 1837, when he underwent long-continued and violent exertion, followed by extreme fatigue, in attempting to keep pace with a noted pedestrian, who was walking against time. To cool himself (for he was in a state of excessive heat and perspiration), he untied his cravat, and walked slowly home. Two days after, he was seized with severe pain in the left side of the face; particularly in the upper-jaw, which became subsequently the seat of it. This attack was at first believed to be owing to the teeth, but upon inspection by a dentist, they and the gums were found to be perfectly free from disease.

* This case has been forwarded to us by a medical friend.

Various local applications, leeches to the face and to the gums, a blister behind the ear, &c. were industriously followed up for a whole week. The pain, notwithstanding, increased in intensity, with irregular remissions and paroxysms during the day; while in the night he was without pain, and generally slept well. He was now placed under medical treatment; and that was assiduously plied and frequently varied, according to the severity and the obstinacy of the symptoms. Nothing seemed to be of any avail in mitigating suffering, or in checking the disease. The boy grew worse. The paroxysms are described to have become gradually more and more frequent, and no longer to have spared his night's rest. At last they left him very short intervals of ease; and the pain was often so acute and insupportable as to throw him into convulsions. At this time his intellect is said to have been impaired; he did not clearly distinguish objects, forgot the names of things, and could not connect his ideas. Whether this condition depended upon the disease or upon the treatment, I know not, as it disappeared soon after I saw him.

When I was consulted, my patient had been ill *above four months*. His general condition was such as has been described. The case presented all the characters of a severe *tic douloureux*. The parts affected with pain presented neither redness nor swelling; there was no preternatural heat; and pressure could be endured. During the remissions, the pulse and respiration were natural. He had a desire for food, but took it sparingly. The evacuations both from the bowels and the kidneys were unhealthy.

Having already prescribed the German mineral waters (as, indeed, I continue to do) with great success in many severe cases of neuralgia, and being well acquainted with other remarkable examples of their efficacy both at home and abroad, I resolved to make trial of them in this instance. The boy having been submitted to a proper course of diet and medicine, as well to free him from the effects of former treatment as to prepare him for the mineral waters, he was directed to begin with two beakers of the Ems Kesselbrunnen of the temp. 117°. When he was found to bear this well, the Carlsbad water was ordered, beginning with the spring of lowest temperature, 122°, and gradually pro-

gressing till he was able to take six or seven beakers of the Sprudel, 165°. After the first week, there was an abatement of pain. In six weeks his health and spirits were restored, the pain having gradually subsided, till it left him entirely. He has been now quite well about a year and a half.

I have the honour to be, sir,

Your obedient servant,

G. S. JENKS.

Brighton, 25th February, 1839.

MEDICAL GAZETTE.

"*Ucet omnibus, Ucet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.*"

CICERO.

MEDICAL CHARITIES.

A LATE eminent individual occasionally suffered under a most singular defect in his vision. When he looked at a word, as, for instance, a name on a door, he could see only one-half of it at a time; and when other men saw *Tomkins* written quite plainly, he read only *Tom* or *kins*. His intellectual faculties, however, were quite sound, so that he never took the half for the whole, and often guessed what he did not see. The mental amaurosis under which our Malthusians labour is of a far more painful kind; if they can see but a third or a tenth of a subject, they immediately draw their pinching conclusions, and should any humane person attempt to set them right, they babble something about surplus population and geometric proportion. The word CHARITY, for example, stands over the portals of a hospital in capital letters; nobody can mistake it; nobody, that is to say, but a disciple of Malthus; he can read only the first two letters, and fancies that they stand for *cheating*. Now we promised in our last article to shew that this is not the case, and that there is no good reason for supposing that the Sheffield (or, in-

deed, any other) hospital is frequently imposed upon.

In the first place, then, why are we to imagine that the persons now commonly admitted into hospitals were not originally intended to be benefited? Do the rules of Guy's or St. Thomas's Hospital, or of the Sheffield Infirmary, ordain that the physician is to chaffer with the sick, to overhaul the day-book of their life with unfriendly eye, and reject four-fifths of the applicants? Is the hard drinking of 1838 to exclude the gastritis of 1839? or is the going to Bartholomew Fair to be incompatible with entering Bartholomew's Hospital? Again, are working men supposed to be inadmissible into any Infirmary on the face of the earth, because they have so few children that they might maintain them, or so many that they might be maintained by them? But, above all, when or where, before the late shivering fit of frigid enthusiasm, was it ever proposed to exclude servants from hospitals? Why it is for this very class that hospitals are eminently necessary! What is to become of an ordinary servant, attacked with fever or acute rheumatism in the house of a middling tradesman? In the golden age, she would have been considered a member of the family; but we live in the iron one, and she is sent home to her friends: and to what a home? Her father is a mechanic, with a wife and three children, occupying a garret in a by-street, with little money, and no spare bed. It seems from the "Inquiry," that fever cases are not admitted into the Sheffield Infirmary; possibly its assumed contagiousness excludes it; but if so, what is to become of the mechanic's family, with every member within six feet of their sister labouring under typhus? It must be allowed, that the idea of a founder becomes sadly contracted in the pineal gland of an economist; instead of measuring Hercules by the

foot—instead of supposing the boundless liberality from the great institution—a Malthusian will hold out his toe, and cry, "Carve me a founder of an Hôtel-Dieu after this pattern—an Edward VI. to correspond with this taper extremity!"

Or, in the second place, if, instead of reasoning upon the sentiments of the illustrious dead, we endeavour to ascertain those of the generous living, we shall find that they are rarely liberal, after the fashion of the economists. Charity with a large alloy of suspicion, may be a good qualification for a relieving officer, but is a very bad one for a contributor to an infirmary. The fact is, that benevolent institutions are not indebted, either for their origin or their support, to the contributions wrung from the cold and the reluctant; they are not watered by the scanty rill miraculously forced from the rock, but by the copious streams which spontaneously descend from the hill-side. The genuine and willing subscriber, who bestows not one guinea from shame, but fifty from love, is not likely to become an exclusionist, or to cry out that hardly any one is destitute enough to enter his hospital. The mere Malthusian, on the other hand, is so fastidious, that no lady ever found it more difficult to match an amber-coloured ribbon than he does to get patients to rival his patterns of perfect misery. Too many children or too few, marriage or celibacy, are equally inadmissible; the colours are a fine canary or saffron, but the real amber tint is wanting.

The old man who exclaimed,

"*Homosum, humani nihil à me alienum puto,*" may have felt that his sympathy with the consequences of human error depend in some measure on his own liability to the cause as well as the effect. The rich landholder of the West Riding recollecting that he was formerly not proof against old port, ex-

tends his indulgence to those who have been frail in gin; and even if the sick poor should happen to be single, or married, without children, he does not say, with the author of the Inquiry, that "These, in the majority of instances, should be made to struggle against their difficulties*." But there is still another point on which we are not at one with the exclusionists; we differ with them as to the interpretation of the social contract. They are ever ready with the cry of "Leave the poor to their own resources," and wish to have it believed that their only resources are the wages given them by express agreement, or their savings from these wages. A labourer in husbandry has eight shillings a week; and out of the superfluous part of this revenue he is to subsist when ill, to provide his wife with an accoucheur, and to lay up a provision for his old age. When the Commissioners for Inquiry into the state of the Poor in Ireland asked the tenant of a cabin if he could save any thing from his wages, he wanted to know "If it was funning the gentleman were?" And it must be owned that many of the Malthusian propositions have the air of a grave joke, and would have done honour to the Dean of St. Patrick's.

Our view of the social contract is as follows:—The labourer receives only eight shillings a week by express bargain; but by an implied though tacit agreement a small addition is made to it, as long as he conducts himself tolerably. Occasional bounties of various

kinds, and gratuitous medical advice when he is ill, are among the usual additions to his scanty wages. Now supposing these gifts to amount, on an average, to two shillings a week, can a man whose heart is any thing more than a pulsation under the fifth rib, deplore the amount lavished upon the thrifless ploughman, and wish that he were left to his own resources? Is it not plain to all whose wits are above the level of a *grudger's*, that when the two shillings have been added to the eight, society has still driven a hard bargain with the rustic labourer, and obtained his endless toil at half its real worth?

We will conclude by remarking, that if any error were unaccountable, it would be that stupid one of the Triumvirate and their hangers-on, who continually repeat that charity degrades its object, as an argument against the old administration of the Poor-law, and, indeed, against benevolence in all its forms; quite forgetting that in England, where public and private charity have always been profuse, the lower classes are more spirited than in those continental states where relief is dealt out with a reluctant hand. Let us hope that some of these icy philosophers practise better than they preach; and as Martial boasted that though his poems were wanton his life was pure, we trust that though the author of the Inquiry writes like a Malthusian, he acts like a physician.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

May 14, 1839.

SIR B. C. BRODIE IN THE CHAIR.

On the Composition and Elementary Structure of the Pus-globule. By GEO. GULLIVER, F.R.S., Assistant-Surgeon to the Royal Regiment of Horse Guards.

In the course of some researches on the properties of the different animal fluids,

* This systematic dereliction of the duty of charity is not recommended merely in the case of drinkers, nor is it enjoined in this place alone. At p. 36 the author says, "The awakening of their own faculties, or the breathing process, by which the mind starts into conscious existence and vigorous exercise, will mainly be accomplished by throwing them upon their own resources. * * * Supposing, in the attempt, debts and obligations are incurred, which compel strict economy, or occasion certain privations. There is nothing hard, cruel, or unjust in this. There would be great cruelty and injustice were it otherwise" (1)

the author has been led to observe certain peculiarities in the structure and composition of the pus-globule, which he believes have not hitherto been described, and which he regards as important, because there are particles both in the healthy and diseased animal fluids liable to be mistaken for those of pus; and we can only expect to acquire a satisfactory knowledge of each, and of their respective uses in the animal economy, by a careful investigation of their specific characters.

The description which the author has given of pus comprehends an account of the physical and chemical properties of two distinct substances, which he says compose the globule. One of these appears to be analogous to coagulated fibrin; while the other would seem to be a proximate animal substance, possessing well-marked characters, and, indeed, giving to pus its peculiar properties, such as its gravity, indisposition to putrefaction, &c.

The author's observations are summarily noted in the following conclusions, viz.:—

1. That the pus-globule is composed of central molecules, generally three in number, connected together by an external part, which gives shape and size to the whole.

2. That the molecules are dense, smooth, and spherical, measuring from 1-10666th to 1-8000th of an inch in diameter; and that they differ from fibrin, and from any part of the human blood corpuscle, in their form, density, indisposition to putrefaction, and complete insolubility in acetic acid.

3. That they are probably of a peculiar nature, and indispensable to the constitution of the pus-globule.

4. That the external portion which surrounds the molecules, so as to complete the pus-globule, is analogous to coagulated lymph or fibrin, being rendered translucent, or dissolved by sulphuric, sulphurous, oxalic, or acetic acids; and the solution in the latter affording a precipitate with ferrocyanate of potass.

The medium diameter of the entire pus-globule appeared, in the author's microscope, to be something between 1-3000th and 1-2500th of an inch, although he observed that there are so many globules of both larger and smaller size than here indicated, that probably no measurement of the pus-globule has ever been given which might not be verified by the selection of some one of corresponding magnitude.

Mr. Gulliver proposes to designate the little central bodies *pus-molecules*, remarking that these can never be confounded with the *pus-globules* by those who have once examined the distinction.

The paper concludes with an incidental

suggestion as to whether some of the substances which are shewn to possess the power of easily decomposing the pus-globule at the moment of its formation, might not be found useful in the treatment of certain obstinate cases of suppuration.

On a new and successful Method of treating Prolapsus Uteri. By BENJAMIN PHILLIPS, F.R.S., Surgeon to the St. Marylebone Infirmary.

The object of the author in the present communication is to recommend a method which he has employed with success in bringing about a diminution in the calibre of the vagina in old cases of prolapsus uteri, and thus presenting an obstacle to the descent of the uterus. He relates the case of a patient in the St. Marylebone Infirmary, in whom the infirmity had existed for several years, and who had been unable to bear the irritation occasioned by pessaries of all shapes and of every material employed in supporting the womb. In this case the author succeeded in giving complete relief by destroying a portion of the mucous lining of the vagina by means of strong nitric acid. The contraction which ensued on the separation of the sloughs reduced the vagina to the size of that of a woman who had never borne children.

Remarks on the Removal of Vascular Tumors by Deligation. By R. LISTON, Esq., Surgeon to the North London Hospital.

The object of this paper is to afford an additional recommendation of a practice applicable to the ligature of vascular tumors, which has been again and again laid before the profession. The author is induced to bring it forward on the present occasion because it was not noticed in the paper of Mr. Tyrrell on *Nævus*, which was read before the society early in this session. The plan alluded to consists in dividing the skin at the base of such tumors before tightening the ligature, in order to avoid including it in its noose. By thus modifying the operation, the author considers that several objections to the use of the ligature are avoided—namely, the intense suffering which attends its application in the ordinary way—the imperfect strangulation of the included mass—the bleeding which sometimes occurs in the separation of the sloughs—and the deformity caused by the destruction of the cutaneous and other tissues.

The author subjoins some cases of the successful application of the ligature in the manner proposed, and refers to others which have been published in the *Lancet* during the last two years.

At the conclusion of the meeting the secretary announced that the next meet-

ing of the society would take place on Tuesday, the 28th, and not on the 21st, as had been erroneously stated in the cards sent round.

A LECTURE

ON

INOCULATION, VACCINATION, AND REVACCINATION,

*Delivered in the Theatre of St. Thoma's
Hospital,*

BY DR. CAPE.

BEFORE closing my observations upon the more important and peculiar diseases of children, I wish to call your attention to the late very general prevalence of small-pox, and the frequent failures of a single vaccination in infancy as a protection against that hideous disease for the whole period of life. I shall endeavour to throw together the principal facts which have lately been brought before the profession; and in doing so, I cannot sufficiently express the obligations we are under to our German medical brethren for their careful statistics on this point; they have shewn themselves in this more practical than usual, and have compensated in some degree for the importation of homœopathy, animal magnetism, and other transcendental nonsense. There have lately been several good papers founded upon these tables in the different medical periodicals of this country, especially in some late numbers of the *Lancet*; but there still exists so much ignorance upon the subject, that the important conclusions to which they lead cannot be too widely diffused.

Those only who have seen bad cases of confluent small-pox, where it is impossible to recognise the features in the mass of black eruption which masks the face, can have any adequate conception of this most horrible and disgusting disease; and the danger to life is as great as it is hideous; for even now, under all improvements, and the best known treatment, from 30 to 40 per cent. of those attacked die: and those who recover are left in a state of debility, predisposing them to fall victims to other diseases, which they might otherwise have surmounted; and it is well known that blindness is more frequently produced by this than any other single cause: hence the blind you see in the streets are so often pitted with small-pox.

The extraordinary mortality of this disease, shewing that it may be much worse than the cholera, plague, yellow fever, or any other affliction to which mankind is subject, was well instanced in 1790, dur-

ing the war against Tippoo Sultaun. He devastated the country of Travancore and Malabar, sending the inhabitants into captivity, according to his usual savage warfare; and among these unhappy beings was a small division of eighty young women, selected for the service of the royal kitchen, to grind corn and other menial offices; these were attacked with small-pox as soon as they reached the mountainous country, and such was the fatality that only one arrived at Seringapatam*.

One of the means practised for a long time in the East to mitigate this dreadful scourge was inoculation, or producing the disease artificially in a healthy person under proper precautions; this, it is well known, was introduced into Europe by Lady Mary Wortley Montague, in 1722; but for the eighty years it was practised, the number of deaths from small-pox was rather increased than diminished; for every patient in whom that process was going on, could communicate the disease in its worst form to others—each was, in short, a focus of contagion; and as it was found impossible to enforce a proper seclusion of the affected, the result was, that inoculation insured a perpetuity and universality of small-pox, inasmuch that the practice was prohibited in Paris, in 1763. In 1786, the Empress Catherine invited Baron Dimsdale from this country to St. Petersburg, and she and her son Paul were inoculated with small-pox matter. This made the practice fashionable; and it became so prevalent in consequence, that, according to Sir Alexander Crichton, previous to the introduction of vaccination, every seventh child born in Russia died of small-pox. But independently of the danger to the community and to the individual, inoculation did not always afford protection against a subsequent and even fatal attack of small-pox. I myself have met with several cases of persons attacked with natural small-pox, who had been inoculated before the discovery of vaccination, and had been very severely affected with the disease; for the artificial disease is sometimes fatal. Indeed, a claim to protection cannot well be maintained for inoculation, when the natural small-pox itself sometimes fails. This was instanced in a virulent epidemic at Copenhagen, where, according to Möhl, one-sixth of those attacked had had small-pox before, and at Marseilles, in 1828, where a greater proportion died of those who had had small-pox before, than of those who had been vaccinated. The same took place in Edinburgh, in 1818-19, and at Norwich, 1819; and as the suscep-

* Vide Col. Mark Wilks, vol. iii. p. 64.

tibility to small-pox and vaccination is the same, a farther proof may be drawn from the successful vaccination of grown persons who were *pitted* with small-pox. Of 297 such, in the kingdom of Wirtemberg, the result was, 95 good, 76 modified, and 126 no effect; or of every 100, 32 good, 26 modified, and 42 no effect; which would leave at least 32 per cent. liable to a second attack.

To this mischief and failure of inoculation, is opposed, in bright contrast, the philosophical and brilliant discovery of Jenner, at the end of the last century—viz. the substitution of a mild and non-contagious disease. Into the history of this discovery it is not my intention to enter; but I will only observe, that there is so close an affinity, so evident and strong an analogy, between vaccination and small-pox, their protective powers being nearly identical, those who have had one, being unsusceptible for a certain time of the other, and those unsusceptible of one being equally so of the other, that I cannot help agreeing with Jenner in considering the two as modifications of the same distemper. The protective powers of vaccination gradually decrease, and the susceptibility to small-pox returns in the same proportion; and again, *re* vaccination succeeds in proportion to the time which has elapsed since the original vaccination. The great resemblance, if not identity, in the course of pustulation; and, above all, the great facility with which every circumstance relating to both can be explained on this principle; these are so many proofs, though I admit not conclusive ones, of the correctness of this supposition.

Notwithstanding the utility of vaccination was recognized by parliament, and by all the great and learned on the conti-

nent, and that medical men in all parts of the world bore the most unequivocal testimony in its favour, there were not wanting enemies to the new plan; and among others who wrote against it were Dr. Rowley, and especially Dr. Moseley, physician to the Chelsea Hospital, who saw, in distinct prospect, an awful aggravation of human ills from the admixture of beastly humours which the cow-mania, as he called it, threatened to inflict us with. Cases were published in which vaccinated persons became covered with hair, and even exhibited horns and a tail; and that of a child at Peckham was cited, whose natural disposition was so brutified that it ran on all fours, bellowing like a cow, and butting with its head like a bull: in short, they wanted to make people believe that the human form divine would end in a species of minotaur.

“*Semibovemque virum — semivirumque bovem.*”

Among other witticisms produced by this idea, is the following:—

“O, Moseley! thy book nightly phantasies rousing,
Full oft makes me quake for my heart's dearest treasures;
For fancy in dreams oft presents them all browsing
On commons, just like little Nebuchadnezzars.
“*There, nibbling at thistles, stand Jem, Joe, and Mary,*
On their foreheads, O, horrible! crumpled horns bud;
There Tom with a tail, and poor William all hairy,
Reclined in a corner, are chewing the cud.”

Still vaccination bore down all opposition by its effects, which were at first extremely striking, as may be seen by those tables.

Total Number of Deaths from Small-pox —

| In the whole Kingdom of Sweden. | |
|---------------------------------|--------|
| 1782 to 1791 inclusive, | 47,587 |
| 1792 — 1801 ——— | 44,184 |
| 1802 — 1811 ——— | 14,904 |
| 1812 — 1821 ——— | 3,309 |

| In Copenhagen, the Capital. | |
|-----------------------------|-------|
| 1768 to 1778 inclusive, | 2,224 |
| 1778 — 1788 ——— | 2,028 |
| 1788 — 1798 ——— | 2,920 |
| 1798 — 1808 ——— | 724 |

For the first five years of the present century there was not one case of even modified small-pox after vaccination, in Copenhagen. In Norway, in 1810, vaccination was rendered imperative by Government; no one could be admitted into any public establishment, nor even be confirmed or married, without a certificate of having been vaccinated; and from that year till 1819 no small-pox epidemic was known. Ceylon for centuries had been so ravaged by this disease, that the inhabitants fled from their towns and villages on its approach in the greatest terror, pre-

ferring the miseries of hunger, and leaving their homes to be overrun by wild beasts; but by the gradual introduction of vaccination it became extinct in the whole of the British possessions in the island; and from 1810 to 1819 the disease was not known. This created an apathy and indifference; the protection was more and more neglected; and the following year, 1820, 7,874 cases occurred, of whom 2 in 5 died, or 40 per cent. This awful punishment induced them again to have recourse to vaccination; and small-pox again disappearing, shewed in a most remarkable

manner the coincidence of the epidemic with the gradual neglect of vaccination.

Jenner was fully aware that vaccination did not protect the individual for the whole period of life; yet many believed that it did, which, as I have already shewn, is attributing to vaccination more than is due to inoculation, or even to small-pox itself. This led to many disappointments, from the number of cases which occurred after vaccination, and which have been gradually increasing since its discovery.

The proportion of secondary small-pox after vaccination, received into the Small-pox Hospital, at King's Cross, to the whole number admitted, was, in

| | |
|---------------|--------------------------|
| 1809, 1 in 36 | } or 1 in 23 in 7 years. |
| 1810, 30 | |
| 1811, 15 | |
| 1814, 20 | |
| 1815, 17 | } or 1 in 4½ in 7 years. |
| 1818, 6 | |
| 1821, 4 | |
| 1822, 3½ | |
| 1838, 2½ | or 2 in 5. |

It must be borne in mind, that the result in this case is much modified by the total number of the vaccinated daily increasing.

These failures are much better looked in the face, and met than by slurring them over by such excuses as imperfect vaccination, bad matter, &c., which it has been of late but too much the practice to do, thereby shutting our eyes to the facts, instead of investigating them and endeavouring to find a remedy.

One of the most obvious means of accounting for the increase of failure, is the deterioration of the matter passing through so many individuals, suggesting a recurrence to the cow; and this is generally thought to be the case, in a certain degree,

by authorities on the continent and in this country, with some few though eminent exceptions. By the kindness of Dr. Bright I received some matter which was taken from the cow by Mr. Estlin, of Bristol, in August last, in the very county whence Jenner originally derived it, and which I have certainly found more active, producing larger and finer vesicles, and more marked constitutional symptoms, than the old: and some medical friends to whom I have given a supply have said that it recalled to them the disease such as they recollected having seen when inserted by Jenner himself. I have kept up a supply ever since, and am always happy in being able to offer it to any one who wishes to make trial of it.

But a more undoubted source of failure, gentlemen, and one to which I wish more particularly to direct your attention, is that the efficacy of the vaccine virus is diminished, and even entirely nullified, by remaining in the constitution of the individual, subject to its changes, and more especially that important modification of the system which takes place at puberty; that eventful epoch of life evidently exercising an important influence in this respect, and putting vaccination to the severest test; the maximum of cases of secondary small-pox happening at the period immediately following it. The evidence of this is so overwhelming as to render it impossible for any one who even takes a glance at those tables to doubt a moment on the matter. They fully prove that the frequency and danger of small-pox is in proportion to the lapse of time after vaccination; affecting with violence grown persons who had been vaccinated in infancy, and sparing infants and recently vaccinated adults.

Cases of Secondary Small-Pox after Vaccination.

| Age. | London. Gregory. | Wurtemberg. Heim. | Copenhagen. Möhl. |
|----------------|---------------------|----------------------|----------------------|
| under 10 | 12 | 94 | 82 |
| 10 to 20 | 242 | 404 | 356 |
| 20 to 30 | 286 | 502 | 209 |
| above 30 | 22 | 22 | 6 |

This liability to small-pox the older the individual is, be it remembered, is the re-

verse of what takes place as a law of the contagion of natural small-pox.

Cases of Small-Pox among those who had neither been Vaccinated nor Inoculated.

| Age. | Norwich. Cross. | Paris. Mathien. | Age. | Copenhagen. Möhl. |
|----------------|--------------------|--------------------|----------------|----------------------|
| under 10 | 520 | 203 | under 2 | 229 |
| 10 to 20 | 7 | 63 | 2 to 15 | 162 |
| 20 to 40 | 3 | 55 | 16 to 25 | 98 |
| above 40 | 0 | 2 | above 25 | 71 |

Again, the mildness of secondary small-pox before maturity is well exemplified

in Dr. Geo. Gregory's Report of the Small-pox Hospital for the year 1838:—

| Age. | Unvaccinated. | | Vaccinated. | |
|----------|---------------|-------|-------------|-------|
| | Admitted. | Died. | Admitted. | Died. |
| under 5 | 42 | 20 | 0 | 0 |
| 5....10 | 37 | 11 | 5 | 0 |
| 10....15 | 30 | 8 | 25 | 0 |
| 15....20 | 104 | 32 | 90 | 6 |
| 20....25 | 105 | 50 | 106 | 17 |
| 25....30 | 45 | 23 | 55 | 8 |
| 30 ...35 | 12 | 7 | 13 | 1 |
| above 35 | 11 | 6 | 4 | 0 |
| | 396 | 157 | 298 | 31 |

From this table, it will appear that the vaccinated formed two-fifths of the whole number admitted; that the mortality among the vaccinated was about 40 per cent.—among the unvaccinated, 10 per cent.—and that was much increased by six of these dying of superadded typhus fever, three of erysipelas, and one of diar-

rhoea; and, above all, it is to be remarked that not one death occurred under 15.

Dr. Gregory states, and no one can speak with more experience and well-founded authority on this subject, that all the severe cases he had seen, without a single exception, occurred 15 years after vaccination.

In Sweden, 1822, 103 deaths occurred from small-pox after vaccination, all above 15.

" 1835, 47 ditto, all between 19 and 35.

Copenhagen, 1828-9, 29 ditto, all adults but one.

" 1832, 10 ditto, all above 22.

" And not one case, much less a death, among those adults who had been re-vaccinated.

This brings us to the last and most important part of our subject—RE-VACCINATION; and here we cannot do better than again refer to the Prussian and Wirtemberg tables, which have been drawn up with such accuracy by order of their enlightened governments.

Result of Re-vaccination in Prussian Army.

| | Total Number. | Successful. |
|---------|---------------|------------------------|
| 1833 .. | 48,478 .. | 15,269 or 31 per cent. |
| 1834 .. | 44,454 .. | 16,679 37 " |
| 1835 .. | 39,192 .. | 15,315 39 " |
| 1836 .. | 42,124 .. | 18,000 43 " |
| 1837 .. | 47,258 .. | 21,308 45 " |

Result per cent. of more than 44,000 Re-vaccinations in the Kingdom of Wirtemberg.

| | Good. | Modified. | No Effect. |
|-----------------------------------|-------|-----------|------------|
| Circle of the Neckar | 57 | 23 | 20 |
| * Ditto, Black Forest..... | 29 | 26 | 45 |
| Ditto, Jagst | 70 | 5 | 25 |
| * Ditto, Danube | 27 | 35 | 38 |
| Throughout Departments | 51 | 18 | 31 |
| Military..... | 34 | 25 | 41 |
| Average | 46 | 20 | 34 |
| To those marked with small-pox 32 | | 26 | 42 |

The marks of a prior vaccination, though perfect, are no criterion whatever as to its protective influence. During the last year there were excellent cicatrices in the very worst cases in the Small-pox Hospital: one had as many as five. When re-vaccination was first practised by the Prussian government, it was only performed upon those soldiers who did not exhibit cicatrices, having the characters indicated by Dr. Gregory, of London; but in consequence of the severe epidemics, it was universally practised without exception: thus in 1837, of 47,258, the gross number re-vaccinated,

37,299 had good marks of a prior vaccination, 6,903 doubtful, [tion, 3,056 no trace, yet the results were—

Regular in 21,308
Modified in 10,557
No effect in 15,393

The effects of re-vaccination are almost as striking as the original introduction of the disease: thus, in the Prussian army there were—

| Cases of secondary Small-pox. | Deaths. |
|-------------------------------|-------------|
| 1834 | 619 38 |
| 1835 | 259 5 |
| 1836 | 130 9 |
| 1837 | 94 3 |

* Mostly children.

mostly recruits, attacked before they could be vaccinated; small-pox being on the increase among the inhabitants of the country generally.

I feel that I could safely appeal to any of the profession who have given their attention to the subject, in saying that the number of those grown people who have been re-vaccinated with success in this country forms a large proportion to those in whom that process is either modified or of no effect—perhaps not quite so large as in the tables you see hung up in this theatre; but I think very nearly so. As far as my experience goes, I should say that one in four is successful, and that the proportion is greater in women.

There are some philosophers who say that the whole structure of the body is changed in identity, by dint of nutrition and absorption, every seven years, and it is perhaps from this crotchety that re-vaccination has been recommended by many to be performed as often, which, in my opinion, is much more than is necessary, or the public would be induced to follow. I should say that, having regard to the preceding facts, all the deaths happening after maturity, *one* re-vaccination is sufficient, and that the age of FIFTEEN, or that of puberty, would ensure generally an effective one, if the protective influence of the first vaccination had been impaired by the attainment of the full development of the body. Of course, if that age be passed without re-vaccination, each year will only make the necessity the stronger; and I have little doubt but that if vaccination and re-vaccination were carefully and universally put in force, no severe case of small-pox would happen; and, with this view, it cannot be too earnestly pressed upon the profession and the public. If I shall have contributed in any respect to this most desirable object by the diffusion of the labours of others, I shall be most amply rewarded.

“OXYGENOUS AERATED WATER.”

SUCH is the name given to a super-saturated solution of nitrous oxide in water, as prepared by Mr. Searle. Our readers may remember this gentleman as having taken a very active and useful part in the investigation of cholera a few years ago. In a little pamphlet which he has just published, he describes as exceedingly grateful the effects of nitrous oxide when taken into the stomach. The “aerated water” is to be had at Savory and Moore’s, Waugh’s, and various other chemists; and, we think, is well worth trying. It is, at all events, a very agreeable sparkling beverage.

CHARLES HENRY ADAMS.

MR. ALCOCK'S PAPERS.

Mr. Alcock's paper intended for this number is unavoidably postponed, in consequence of the engravings not being ready. We have pleasure in directing attention to this valuable series of papers—more especially to those “On Injuries of the Head and Spine,” which contain doctrines considerably different from those generally advocated.

NOTICE.

Mr. Borthwick's letter appears to us to be unnecessary after the explanation already entered into.

WILSON & SON, Printers, 57, Skinner-st., London.

(EXTRA LIMITES.)

A LETTER
TO THE
EDITOR OF THE MEDICAL GAZETTE,
IN REPLY TO
DR. HAMILTON'S OBSERVATIONS.

By EDWARD WM. MURPHY, A.M., M.D.

Late Assistant-Physician Dublin
Lying-in Hospital.

SIR,

THE observations of Dr. Hamilton on my paper in the Dublin Journal are of such a nature, that my first impression was to suffer them to pass unnoticed; however, as statements and charges emanating from the professor of a distinguished university receive an importance from the position of the accuser which they could not otherwise obtain, it is with much reluctance that I resume, in the pages of the MEDICAL GAZETTE, a discussion carried on through the medium of the Dublin Journal quite long enough for any useful purpose. So long as the collision of opinions may have the effect of eliciting truth, controversy is useful; but when it degenerates to mere angry altercations, it becomes only a struggle for victory; and the more violent the contest, the more is its utility destroyed, and the more does the unprejudiced observer become indifferent to the result. Such appears to be the point to which the controversy above alluded to is fast hastening; and were it not for the reasons already stated, I would willingly leave the reader to form his own opinion from what has been already written on the subject.

Having entered into a full examination of Dr. Hamilton's letters, with as much freedom from asperity as the subject would admit of, and having abstained from any language which could be interpreted as disrespectful to Dr. H. (unless, indeed, exposing the weakness of his assertions, and his unfair manner of supporting them, be considered in that light), I confess I read with no little surprise

what Dr. H. intends for a reply, which, without touching a single argument I had advanced, or disproving the facts I had brought forward, makes up the deficiency by "Specimens of Dr. Murphy's misrepresentations;" "Evidences of Dr. M.'s ignorance of the principles of midwifery;" and "Proofs of the dangerous tendency of the modes of practice in laborious labours advocated by Dr. M. and his late master."

It is scarcely necessary for me to do more than to expose this expiring effort of Dr. H.'s, apprising the reader that it has about as much to say to the real question at issue as it has to the merit of a calm and rational document. A very brief statement will inform the reader what that question was, as well as the grounds which led me to its examination. Dr. Collins having had charge of an extensive hospital, in which there was the widest field for observation which could be desired, published a report of his practice, in such a manner as would be best calculated to condense in a reasonable space the immense body of facts which came under his notice. In doing so he did not seek the empty reputation of detailing a lengthened account of his successful cases, but rather, for the purposes of truth, gave a brief outline of his practice, merely enumerating the cases, in most instances, where that practice succeeded, and giving the leading particulars of those in which it failed. In order that all might be given, it was necessary that each should be curtailed; and thus a work was published which, to the attentive inquirer, afforded much valuable information, but to the superficial reader, in some parts, would seem to be only a collection of bad cases. Amongst many other subjects, Dr. Collins treated of the management of tedious and difficult labours. He states as the result of his experience of the duration of labour, that "we must be guided as to the propriety of giving assistance chiefly by present symptoms and previous history, and not by the length of the labour, as some will suffer more in thirty

hours than others in ninety*." That "he considers the forceps quite inapplicable where the head becomes fixed in the pelvis, and that the ear cannot be reached except by violence, in consequence of disproportion existing between the head and the pelvis, either owing to the former being unusually large, or the latter under size; in most instances measuring little more than three inches from pubes to sacrum, and in others less than this†." In discussing the treatment of those difficult cases which may require perforation, he objects to the practitioner forming his estimate of the existing disproportion by vaginal examinations, or to make it a ground of interference. "That so long as the head advances ever so slowly, the patient's pulse continues good, the abdomen free from pain on pressure, and no obstruction to the removal of urine, interference should not be attempted unless the child be dead‡." In those cases of laborious and difficult labour, when the head does not advance, and the disproportion is so great as to require the perforator—if properly managed, the death of the child takes place before the symptoms become so alarming as to cause any experienced physician to lessen the head§; and hence infers the great value of the stethoscope in giving an earlier intimation of that event than can in any other way be ascertained.

Soon after the appearance of Dr. C.'s work, Dr. H. published his "Practical Observations," in which doctrines diametrically opposite to these are given as the result of half a century's experience. "That the first stage of labour should be completed within fourteen hours, and the whole labour in twenty-four, reckoning from the beginning of the labour throes||." "That if the infant becomes wedged in the passage, and be within reach of the forceps, "the practitioner is imperiously called upon to interfere, before there is a probability that the pressure may destroy the infant's life, and certainly before any untoward symptom threaten the mother¶."

That the forceps, if properly employed, can do no harm, "while, by diminishing the bulk of the infant, it enables the practitioner to lessen as well as to shorten her sufferings;" and as an explanation of this precept, it may be added, the objection made to Dr. Collins is, "that the instrument employed (by him) had certainly not been calculated to lessen the head of the infant to the degree which it can bear

with impunity—viz. to three inches between the parietal protuberances*." "Dr. H. cannot imagine a case of laborious labour, which had been much protracted, where the knowledge of the state of the infant can be necessary to regulate the practice. If circumstances permit the safe use of the forceps, that instrument should be employed, admitting the necessity for interference, whether the infant be dead or alive; or, on the other hand, if, from previous mismanagement or other circumstances, it would be unsafe to use that instrument, it ought not to be ventured upon, even though the infant be alive†." Hence Dr. H. inferred that the stethoscope was useless. Such were the questions to decide; and when the opportunities of experience claimed by Dr. H. are considered, and the importance of these practical points are estimated, the interest which would attach to Dr. H.'s work, had he, like Dr. Collins, given a candid record of his practice, and built his assertions solely upon the facts brought forward, may readily be supposed. In place of this more natural method, Dr. H. adopted one as disingenuous as it was useless. Dr. Collins's work is made to support Dr. H.'s opinions by a perversion of criticism, and an ingenuity of quotation, which Dr. H. alone could effect. Passages in which Dr. C. speaks of those cases in which the disproportion is so great as to require the perforator, and the symptoms of danger indicating its necessity given, are all advanced by Dr. H. to prove, "by Dr. Collins's own shewing, (p. 105, Part ii.), the injurious effects of protraction, where there is little or no disproportion. In fact, the most part of Dr. C.'s directions for the management of cases of great disproportion‡, are quoted and criticized in Dr. H.'s section on the second order of laborious labours§, which include all cases where there is little or none; and not only so, but the very cases which, in consequence of great disproportion, were delivered by perforation, are referred to by Dr. H. as proofs of the injurious consequences of procrastination, in cases of that order. So complete a perversion of Dr. Collins's sentiments and practice obliged him again to explain his views, and to point out these errors in the Dublin Journal for March 1837, to which I refer the reader for a more complete *exposé*. Dr. Hamilton replied to Dr. C. in three letters, addressed to the MEDICAL GAZETTE||, 1837; and if he considered himself aggrieved at "an attack so unex-

pected and uncalled for," as he represents Dr. Collins's paper to be, he certainly took an ample revenge. Under the transparent disguise of upholding his precepts, he selected a few of the worst of these cases, and on the strength of his own reading of the brief outline which was given of them, gave vent to animadversions in which few professional men would indulge, but which would be quite sufficient to appease the most splenetic temper. Of these letters Dr. Collins took no notice, and the controversy appeared to have ceased. But "*ecce iterum Crispinus*." In the year following (1838), Dr. H. addressed a letter to the Editors of the Dublin Journal, under the pretext of instructing the Irish students in the truth of his opinions; but which, in fact, was merely a second edition of the same cases, with more copious notes, equally unprovoked as they were discreditable*. "This Dr. M. has called inviting a controversy;" and without any burst of affected indignation against calumnies and misrepresentations, for which Dr. H. has given quite sufficient cause, Dr. M. appeals to the facts themselves for evidence. A perusal of Dr. H.'s first letter to the Dublin Journal will satisfy the reader whether Dr. H. meant to defend himself from calumnies, or to censure the practice of the Dublin Lying-in Hospital. Labouring as I am under the delusion that the latter was the fact, I again reiterate "the absurd charge" that Dr. H. ought to have published a faithful record of his practice in the Edinburgh Hospital, before he hazarded gratuitous censures upon a practice of which he had no other cognizance than a mere abstract of cases, which he misunderstood, and many of which I have proved him to have misrepresented. The appearance of Dr. H.'s letter rendered a reply unavoidable; to which Dr. H. rejoined in a manner nearly similar to this his last effusion. Unable to meet Dr. C.'s arguments, he charges him with misrepresentations, falsifying of records†, &c.

* Amongst many charges of negligence and inattention on the part of the medical officers of the Dublin Lying-in Hospital, which Dr. H. indulges in, of one of the cases he observes, "Had the circumstances narrated in this case occurred in England, in a parish workhouse, the conduct of the medical attendants would undoubtedly give rise to subsequent inquiry."—*Dublin Journal*, vol. xiii. p. 214.

† Dr. H., in allusion to my "reiterating the absurd charge," says, "This he (Dr. M.) has the *hardihood* to do, after Dr. H. has convicted his late master of a deliberate falsification of the records of that hospital, by suppressing half a sentence, and by interpolating certain words." The foundation of this assertion is as follows:—At the conclusion of Dr. H.'s last letter to the MEDICAL GAZETTE (August 19th, 1837), he intended "to surprise the gentlemen connected with the great establishment in Dublin" with the fact,

&c.; and waxing wroth on those fancied injuries, declares he can have no further communication "with that individual."

In May 1837, a paper was inserted in the Dublin Journal, on the management of the first stage of labour, for the purpose of determining, if possible, contradictory rules of practice, by the results of practice itself, taken in the most extensive range. In it reference to the opinions of Dr. H. had been made, and applied to the test of recorded facts. On one point it appeared that Dr. H. had been misrepresented; and the consideration of the remaining stages of labour was delayed until, along with other opinions, those of Dr. H. could be examined with more certainty; that, however, soon became impossible; "confusion became worse confounded;" and finally, as Dr. H. complained of misrepresentation, had objected to the test to which I applied his doctrines, as being data upon which "no logical reasoner could place any dependence," and had given a most erroneous view of the practice of the Dublin Lying-in Hospital, it appeared to me more advisable to examine separately Dr. H.'s opinions, arguments, and facts. I shewed the ambiguity which led to misrepresentation, examined Dr. H.'s objections to the test of hospital reports, pointed out the erroneous conclusions which must follow by arguing from particular cases as to a practice of which the whole results had been given, and proved that even these cases were, in many instances, misunderstood and unfairly commented upon. In doing so, I

that by a report presented to the managers of the Edinburgh General Lying-in Hospital, 15,936 women had been delivered previously to Oct. 1836, at the very small expense (not annual) of £10,214 13s. 8d. Where were they delivered? No distinction into classes was made, and this astounding enigma would have remained unexplained had not Dr. C. met with an annual address of the year 1834, by which it appeared that up to that period "5193 patients have been delivered in the hospital, and 9,126 out-patients have been attended at their own houses, at an expense not exceeding 9,650l." Dr. C. immediately, in reply, stated that "only 5,193 patients were delivered within the walls of the Edinburgh hospital," and Dr. H. retorts by charging Dr. C. with the omission of the half sentence which referred to the out-patients, and interpolating the words "within the walls," as if that was not essential in order truly to estimate the expense comparatively with the Dublin hospital, from which question, in thimble-rig fashion, Dr. H. slips to the number of cases attended by the medical attendants; not the number of patients supported in the hospital. Dr. H., in the first instance, should have stated fairly the number of patients in each class, and not, by giving only the aggregate, make it appear that there was only one. He now repeats this charge, though he acknowledges never to have looked into Dr. C.'s reply to it. Perhaps Dr. H.'s "two intelligent friends" could supply him with some epithet to characterize such conduct: certainly the word "hardihood" is inadequate.

am not conscious of having indulged in any personalities; nevertheless, to that article is the reply which has appeared in the 27th No. of the MEDICAL GAZETTE.

From this brief history the reader can readily judge of the importance of the practical questions to decide, as well as the opportunity that was offered, had Dr. H. adopted a different course, of determining rules of practice by a strict and impartial examination of facts brought forward on both sides. They were given only on one; and the very candour with which they were stated has been the means made use of to misrepresent them. It has given Dr. H. the opportunity of compensating for the total absence of any evidence of his own, by selections from the worst part of that brought forward by Dr. Collins. While we have, therefore, Dr. C.'s valuable treatise to aid us, by a comparison of opposite facts, in forming an opinion of one mode of practice, we find in Dr. H.'s little more than positive assertions, without a shadow of evidence to help us in investigating one altogether different.

If Dr. C. states as the result of his experience, "that we must be guided as to the propriety of giving assistance by present symptoms, and not by the length of the labour," and refers his reader to the whole of his facts *pro* and *con.*, to form his own opinion; Dr. H., on the other hand, insists "that the sufferings of the women should almost never be allowed to continue longer than twenty-four hours, reckoning from the beginning of true labour throes" (p. 42, Part ii.)—states strongly the fact that "no patient under his care, for thirty-five years, had been above twenty-four hours in labour, and excepting in cases of disproportion none so long;" and silences every doubt by an appeal "to the testimony of the public opinion of the city of Edinburgh*." On such a basis it is evidently not very easy to maintain a controversy; and Dr. H. finding the whole weight of evidence both of the Dublin and other lying-in hospitals against him, and that he has nothing to oppose to it but the worst of Dr. C.'s crotchet cases, and the above rather equivocal test, with the skill of a practised tactician he changes his ground, takes up a position where his opponent in his own defence must follow him, and which, at the same time, gives Dr. H. the opportunity of making this new demonstration a cover for his retreat.

Such, in the present instance, are Dr. H.'s tactics; and while I find the arguments and facts brought forward in my former paper perfectly untouched, I have

now to meet the Doctor on charges of misrepresentations—assertions of ignorance of midwifery, &c. &c.; which, of necessity, must receive an answer as remote as possible from the question which had been under discussion. The reader, therefore, will pardon me for occupying his attention with merely personal considerations, and will, I feel assured, grant to me an impartial attention while I examine Dr. H.'s statements.

The first charge of Dr. H. is against the Editors of the Dublin Journal, to which they are, of course, quite competent (if they please) to give him a satisfactory reply. But certainly Dr. H. must have supposed them to set a very moderate value on the character of their journal, to have admitted "observations" so completely personal as those I am about to notice, in reply to a paper not containing a single personality. A charge of "having given insertion to observations misrepresenting and falsifying doctrines," and "of sanctioning misstatements," comes well from Dr. H., to whose first letter they had given insertion, notwithstanding he had previously replied to the same letter through the MEDICAL GAZETTE; the contents of which (though unknowingly to them at that time) was precisely of the character above described.

It is hardly necessary for me to allude to Dr. H.'s attempt to shift from himself the onus of having invited a controversy which appears not very likely to terminate to his advantage. The facts which I have stated speak for themselves, and, if the reader have any doubt on his mind, a perusal of the letter alluded to will abundantly satisfy him. Having thus disposed of Dr. H.'s "preliminary remarks," I have to consider *seriatim* Dr. H.'s three propositions. "Firstly, Dr. H. lays before the reader a few specimens of the most flagrant misrepresentations, with which he charges Dr. Murphy;" the first of which is most uncandidly alleging an identity of practice between Drs. H. and Burns, on the subject of artificial dilatation of the os uteri. In reply to this I have to state, that before that paper appeared, Dr. H. had already denied artificial dilatation to be his practice, and founded upon that denial a charge of misrepresentation against Dr. Collins, in which I was equally involved. So far, therefore, was I from assuming an identity of practice (once being denied) between Drs. H. and B., that on the fact of their not being identical I proved, from the extreme ambiguity of Dr. H.'s language, the mistake into which I had been led; and after having quoted passages from each author to prove it, I added, "It is essential to point out these ambiguities, in

* Dublin Journal, vol. xiii. p. 204.

order to shew the source of those misrepresentations of which Dr. H. so much complains.* Had Drs. H.'s and Burns' practice been identical, Dr. H.'s language would not have been ambiguous.

The second instance of misrepresentation, is, that "Dr. M. has given a most garbled and disingenuous report of Case 210, p. 465," (Collins). The case to which Dr. H. alludes is one of seven already detailed at length in Dr. H.'s letter, to which I was then replying. I therefore did not give the case again at length, but only so much as would explain my meaning; but at the same time, to prevent the possibility of such a charge as Dr. H. has made, I gave, not only the number of the case in Dr. Collins's work, but also the letters under which Dr. H. had arranged them. I find this case thus stated:—"The first is No. 210 (Case A), p. 465 †." If I am liable, therefore, to Dr. H.'s accusation, I willingly admit that I have been most unintentionally guilty of "habitual misrepresentations;" as none of those cases to which I referred were given in full. But I am charged "with having suppressed certain important facts ‡ which are necessary to render it intelligible, and also of having founded, upon the suppression of those facts, certain injurious accusations against him," (Dr. H.).

"Firstly, Dr. M. says that the woman had been in labour from the 20th till the 23d of February; whereas the record bears, that 'she was admitted on the 17th, with the liquor annii dribbling away, and that pains began on the 18th, and continued on the 19th.'

"Secondly, he has suppressed that, 'on the 20th the head of the child was found low in the pelvis, the edges of the os uteri thin and lax, the pains had returned in an urgent form,' and that 'the woman had expressed herself as suffering the most acute distress.'" The record bears—that "a woman of a most fretful and anxious disposition was admitted, February 17th, to be confined of her first child. On the night of the 18th she complained of *pain and uneasiness, which she supposed was her labour*; yet there was no dilatation of the os uteri. The next day (19th) she still complained of *some uneasiness*, but slept the entire of that night. On the morning of the 20th the *pain and uneasiness* returned in a more urgent form, and she

expressed herself as suffering the most acute distress; still there was *no dilatation of the mouth of the womb*; it was quite thin and lax, and the head was low in the pelvis. The pain continued during the night. The following morning (21st), at 9 A.M., the os uteri was dilated to the size of half-a crown, but the pains had not assumed a bearing-down character.*"—Thus the pains, which "began on the 18th and continued on the 19th," are described in the record "as pain and uneasiness, which *she supposed* was her labour; that on the next day she still complained of *some uneasiness*, but slept the entire of that night; that even on the 20th the same pains returned, only in a more urgent form, nor was there any dilatation of the mouth of the womb until the following morning (21st), when these irregular pains merged into regular, though feeble, uterine action. Now Dr. H. has "the extraordinary temerity," (to use an appropriate phrase of Dr. H.'s,) to charge me "with suppression of certain important facts of this case;" and in the charge he advances is guilty of the very act of which he complains. He gives as the record, a form of words not in the record, and omits altogether, that though the os tinea was lax and thin, there was no dilatation of the mouth of the womb on the 18th, 19th, or 20th; which, together with the irregular character of the pains (being described as much a sense of uneasiness as of pain), proves regular labour not to have commenced. This is the *more remarkable*, because Dr. H. is perfectly aware "that spurious pains are apt to precede true ones, not only for hours but for days," and gives the following means of distinguishing one from the other:—"The author is most anxious to explain to the junior part of the profession especially, what is meant by protraction of the first stage; for he is every year called in to cases where great mistakes upon this point are committed, chiefly in consequence of supposing spurious pains to be the true pains of labour. He has already hinted at the means of distinguishing the two, and he now repeats, that *spurious pains are irregular in their recurrence, and that they produce no influence upon the edges of the os uteri*."

The reader can readily decide what would have been even Dr. H.'s estimate of the duration of labour in this case, had it been in his charge, and can therefore appreciate the value of his first and second accusations. The two remaining facts that I am charged with having suppressed, are,—

* Dublin Journal, vol. xiv. p. 403.

† Ibid. vol. xiv. p. 426.

‡ As an instance, "inter alia," of the suppression of important facts of a case (No. 150, p. 464), Dr. H. remarks, that "Dr. Murphy has suppressed the most important fact, that the scalp of the infant was allowed to *protrude through the external parts* for nearly twelve hours." I have only to say, that there is no such fact stated in the case.

* Collins, p. 465.

† Hamilton, p. 222, Part 1.

"3dly. In the authentic record it is stated, that, 'on the morning of the 23d, the pelvis felt of sufficient size to allow the head to pass, and all that seemed wanting to effect this was that the pain should become expulsive;' a circumstance carefully concealed by Dr. Murphy."

"4th. The following report of the case, at 9 P.M. of the 23d, is also suppressed by him:—'On examination, the head was found in the same situation as in the morning; and had it not been that the mouth of the womb still remained over it next the pubes, an attempt would have been made to deliver with the forceps.'"

Here also Dr. H. omits the very next sentence that follows the word "forceps,"—viz. "the head was immediately lessened, and almost every bone removed before it could be delivered." No forceps, therefore, (excepting, indeed, Dr. H.'s,) could have delivered a head which the crotchet could hardly extract. Dr. H. is also perfectly aware of the importance of such a fact, because, without even mentioning the statement itself, he makes an ingenious attempt to get over the difficulty it obviously presented to him. In his explanation of this "most melancholy case," he makes it abundantly simple by gratuitous assertions, for which there is not the shadow of a foundation. He assumes, "that the pressure of the head produced such a swelling of the soft parts as to oppose a serious obstacle to the extraction of the infant." "Of course (says Dr. H.) this swelling subsided after death, and could not be discovered by dissection." But why could it not be discovered before death, when, on the morning of the 23d, the pelvis *felt* of sufficient size to allow the head to pass, and all that seemed wanting to effect this was that the pains should become expulsive; and when, in the evening, the forceps would have been tried, but that the dilatation was not completed? Knowing the circumstances under which Dr. C. used the forceps, such a swelling would have been in itself a prohibition. Such are the four charges of suppression of important particulars which I have made: "fortified by which, Dr. M. has had the extraordinary temerity to prefer (what Dr. H. pleases to call) the following accusations," which, notwithstanding that the important particulars are now given, Dr. M. most distinctly re-asserts:—

"1st. That Dr. H. gives this case as being of ninety-six hours' duration, though there was no dilatation of the os tincæ till the 21st—sixty hours before delivery.

"2dly. That Dr. H. asserts the cause of delay to be interception of the cervix uteri, though at no period of the labour did the

pains become expulsive, and, throughout, the uterus acted imperfectly; the head, therefore, could not have been forced down upon the pubis, so as to intercept the cervix. Dr. H. has therefore assumed a condition of which there is no evidence." This assertion has kindled Dr. H.'s ire so completely, that he seems to have a difficulty, amongst the many epithets which were no doubt pressing themselves into his service, to find terms "which a gentleman would choose to employ," to give vent to his indignation. I cannot explain why the above assertion should have so much disturbed Dr. H.'s equanimity; as he has, however, alluded to it under another head, I shall take no further notice of his observations here, than to state that Dr. M. never asserted that the uterus was not *interposed* between the head of the infant and the bones of the pelvis.

"3dly. That to complete, in little more than two hours, a labour where the pains were so weak as scarcely to produce any effect on the os tincæ, and the utmost difficulty experienced in extracting the child, even when the head was broken up, is a degree of skill which requires something more to make it intelligible than mere assertion." Dr. H. observes, I could not have preferred this very modest insinuation had I not concealed from my readers that the pelvis *felt* of sufficient size to allow the head to pass, and all that seemed wanting was that the pains should become expulsive. Neither could Dr. H. have preferred this well-supported charge, had he not also concealed from his readers the fact, that there was the utmost difficulty in extracting the head with the crotchet, at the very time that the pelvis *felt* of sufficient size to use the forceps; of the importance of which fact he was perfectly conscious.

The next charge of misrepresentation is in reference to the use of the stethoscope. Dr. H., in his letter to the Dublin Journal* (No. 38), quoted eleven cases; two (Nos. 32 and 1091) to prove the injury of delayed delivery while the foetal heart was acting, and nine to shew the effects of delay for some hours after it ceased. Of the first class, Dr. H. stated that other cases may be quoted, to prove that several women's lives in the Dublin Lying-in Hospital were brought into great jeopardy while the child, according to the evidence of the stethoscope, continued to live..... And yet (observes Dr. H.) the following cases (the nine) shew that the principle was carried still further in the Dublin Lying-in Hospital; for it is admitted, that notwithstanding the alarming symptoms, the sufferings of the patient were allowed to

* Dublin Journal, vol. xiii. p. 223-228.

continue for hours after the death of the infant was believed to be unequivocally ascertained by means of the new method. It may be observed here, that delivery was not effected for some time after the first cessation of the foetal heart, in order that the death of the infant should be unequivocally ascertained by means of the new method. Of the nine cases quoted by Dr. H. but one was fatal, though they were all extracted from a section containing only cases of extremely severe labour, requiring to be delivered by the crotchet. Dr. Collins at once exposed the weakness of this proof. To which Dr. H. replies, as usual, by a charge that Dr. C. "had suppressed the important fact that I (Dr. H.) had copied nineteen cases of that description, and that eight of the women died." A list of these nineteen cases was given, and in commenting upon it, in my former paper, I pointed out four objectionable cases amongst the deaths, and three omissions among the recoveries. On this Dr. H. founds his charge of misrepresentation, to part of which I plead guilty. Of the three cases I asserted to have been omitted from the recoveries, two had been enumerated (725 and 1041); and the third (1033), I freely admit, does not come within the terms of the allegation, that the sufferings of the poor women were allowed to *proceed for hours* after the foetal heart ceased. The reader will, I am assured, give me credit, when I state that the mistake arose purely from inadvertence in copying lists. But that Dr. H. should assert, that I should adopt so shallow a pretext for imposing on the credulity or supposed ignorance of my readers, when he acknowledges to have committed a precisely similar mistake, but of a far more mischievous effect, and claims that it be considered "a very unintentional error*," is only one of the many proofs which his "Observations" afford of the intemperance into which the embarrassment of his position has betrayed him. Of these nineteen cases, therefore, the recoveries are, as Dr. H. stated, but eleven. Now let the deaths be examined, and, of the eight given in the list, I find I am indebted for five in place of four objectionable cases to Dr. H. Two deaths are again repeated, without note or comment. One (665) a case of puerperal fever, another (605), of which the details are not to be found; and this after the error had been pointed out. Two more Dr. H. attempts to justify. No. 32 he again enumerates, to prove the above allegation, though it is distinctly stated in the case, as Dr. H. has quoted it, "that the foetal heart having ceased to beat, she was delivered by the

crotchet." In No. 1091, no operation was required, the woman being delivered naturally. In the remaining case (173), the words "the child was evidently dead, and the pressure on the urethra very severe" (the latter sentence omitted by Dr. H.), are given as reasons for immediate delivery. These eight deaths, therefore, when strictly examined, amount just to three, making the proportion of deaths to recoveries 3 to 11—nearly the same as had been stated*.

But while Dr. H. declaims in terms needless to characterize against misrepresentations in his list, he passes by the real objection made to it—viz., that being only a list of selected cases, the ratio of mortality must be inaccurate, even if the list itself were unobjectionable. I stated that "16 of these cases are taken from Dr. Collier's section on Still-born Children, in which is given a short outline of such as possessed most interest in 106 cases of *extremely severe labour*. In this outline *every one* of the cases in which the mother died is detailed or referred to, while several who recovered are only numbered. There were altogether 79 crotchet cases and 15 deaths, of which 3 are related in the chapter on 'Tedious and Difficult Labour;' the remaining 76 are included in this section, of which 41 are detailed, and, among them, all the other deaths which occurred. Beside these, are 30 others (of which 9 cases are given, and 2 deaths). So that among 106 cases of extremely severe labour, there are but 14 deaths, or 1 in $7\frac{1}{2}$; while among 79 delivered by the crotchet, there are 15 deaths, or 1 in 5, in all of which the child being some time dead, or the urgency of the symptoms, were the motives of the operation. From this section Dr. H. has extracted 27 cases, of which 11 are deaths; and from this extract is chiefly formed this last list of 19 cases and 8 deaths†." All these cases being similarly treated to those selected by Dr. H., it is evident that any ratio of mortality can only be derived from the whole. I find it now necessary to add the results of forceps cases, which altogether amounted to 24—14 being for tedious labours, and 10 for complicated. Of these, 4 women died—"not from any injury connected with the delivery‡"—and 8 of the children were still-born. Notwithstanding, however, that the proportionate mortality of crotchet cases had been already given, the great majority of which operations were performed in consequence of such great disproportion, that "after the most patient trial the imprac-

* Cases are No. 126, p. 158, II; 477, p. 817, AA; 481, p. 1038, D.

† Dublin Journal, vol. xiv. p. 422.

‡ Collins, p. 15.

* Vide note, p. 22, MEDICAL GAZETTE.

ticability of delivery being safely effected" was clearly proved, yet Dr. H., anxiously seeking for misrepresentations, has not only made no attempt to disprove it, but, in perfect consciousness of its truth, does not hesitate to assert that "*every fourth woman on whom the perforator and crotchet were had recourse to, died†*," and on this misrepresentation manufactures the "appalling fact," that thus in 103 (79 + 24) cases of laborious labours (of the 2d and 3d orders), 24 women and 87 infants were lost, making 111 deaths in those cases of protracted labour. These 103 cases consist of 79 crotchet cases (Dr. H.'s 3d order), 14 forceps cases (Dr. H.'s 2d), and 10 forceps cases of *complicated labour*! and the 111 deaths is made out by the addition of 87 (79 erot. + 8 for.) deaths of infants to (15 crot. + 4 for.) = 24 (!) deaths of mothers. When, therefore, it is considered that the total mortality of mothers amounts to 19, not 24—that of these, 4 belong to forceps cases of two different classes, without any statement as to which they belong—that to this number 24 is added 87 infants, 79 of which were crotchet operations—and of the remainder, some, if not the most part, must be for complicated labours—and all to make a grand total of 111 deaths in 103 cases. The reader will perhaps admit that Dr. H. was sadly straitened for "an appalling fact," and should have been the last to hazard a charge of flagrant misrepresentation. To say the least of it, it is strange to find the medical professor of an established university descend to charge two physicians who had held the respectable situations of master and assistant to the Dublin Lying-in Hospital with having deliberately misrepresented his work by means of garbled extracts and other artifices, and he at the same time guilty, without even the excuse of ignorance, of the very charges he has made—without referring to former instances left unanswered by Dr. H., and taking the evidence alone of his last "Observations;" when he is found to suppress an important fact, in order to sustain a charge of suppression of facts; to re-state one case (605) not detailed, and another inapplicable (665), without remark after the error had been noticed‡, and this to support a charge of "imposing upon the credulity of the reader;" to quote a case as proof of a fact not stated in the case; to give, by a very shallow artifice, a most distorted view of the proportionate mortality in laborious labours; and at the same time to remind us "that sinning against the ninth com-

mandment is universally admitted to be a transgression of a heinous character." He gives evidence of such recklessness in asserting that its very inconsistency encourages a willing doubt that Dr. H. in his cooler moments would not so commit himself. Were it not that Dr. H. had been labouring under the irritation consequent upon his inability to escape from the difficulties with which he found himself surrounded in attempting a reply, he would hardly have been betrayed into the absurdity of quoting a case (No. 32) in which it is said "that the action of the fetal heart having ceased to beat, she was delivered by the crotchet"—which evidently implies a delivery consequent upon its cessation—and coupling it with a case (1091) where no operation at all was required, observe, "if these be not the cases where the poor women's sufferings were allowed to continue for hours after the death of the infant had been ascertained by the stethoscope *," Dr. H. certainly does not understand the English language.

If Dr. H. had not already sufficiently proved his knowledge of the English language, seemingly as familiar with the Dictionary of Gross as of Johnson, and having equally at his command the most courtly phraseology and the language of Billingsgate, his claim would be materially endangered if it depended upon the truth of the above hypothesis. But Dr. H. seems so completely blind to his position, that I cannot help wishing,

"O, wad some power the giftie gie us,
To see oursel's as others see us,
It wad fra mony a blunder free us,
And foolish notion;
What airs in dress an gait wou'd lea'e us!
And e'en devotion."

The next topic which Dr. H. has introduced is, "Evidence of Dr. Murphy's Ignorance of Midwifery." On this subject I freely confess that I do not feel myself so completely perfect as to refuse a useful hint even from Dr. H., no matter what may be his motive in enlightening me. I would most willingly adopt the precept, "*fas est et ab hoste doceri*," and endeavour to profit by his lessons, though they were accompanied by some disagreeable though salutary castigation. But, with every desire to learn, I regret to find I am obliged most unwillingly to instruct. The first evidence of my want of knowledge is in reference to interception of the cervix uteri. "In page 431, Dr. M. has the following words:—Pressing on or supporting the anterior edge of the os tinea would of necessity act against the head just in the same way as if two fingers were applied to the head itself, and the

* Collins, p. 488.

† No. 27, MED. GAZETTE, p. 30.

‡ Dublin Journal, vol. xiv. p. 422.

* MED. GAZETTE, No. 27, p. 26.

difference in both cases, where the uterus and not the fingers effect the dilatation, is so slight as to be immaterial; but when the practice is applied where there are no strong forcing pains, and the fingers are, as it were, to supply the place of the uterus, it in no way assists us in understanding how it is to be done."

"This sentence (says Dr. H.) seems to impart that it is Dr. M.'s opinion, that pressing with two fingers on the head of the infant during the labour pains has the same effect as pressing upon the anterior edge of the os uteri—he having evidently not understood that during labour the head of the infant is passive, and the uterus the active agent." This is a curious inference from a passage stating "that the difference in both cases, *where the uterus and not the fingers effect the dilatation*, is so slight as to be immaterial."

It is first necessary to determine what Dr. H. means by interception of the cervix uteri, which may be collected from his "simple explanation" of case 210. He says, when, on the 20th of February, the child's head was found low in the pelvis, the uterus must have been *interposed* between it and the bones of the pelvis. This Dr. H. has called intercepted, and he sees no reason to alter the expression—(p. 25).

What Dr. H., therefore, calls interception is found in all cases of prolapsus uteri, and especially in the kind of case which has led to its discussion—one in which the waters dribbling away early is followed by spurious pains, and the woman making fruitless attempts to force her labour, only drives the undilated uterus down into the pelvis. But that this of necessity intercepts the cervix, is an opinion I believe peculiar to Dr. H. Burns seems unconscious of it; and as I have no desire to become preceptor to the professor of a university, I the more willingly adopt his language. "Labour (he says) may also be rendered tedious by the different stages not going on regularly, but efforts being prematurely made to bear down. In consequence of these, the uterus descends in the pelvis before the os uteri be dilated, and the process is often both painful and tedious. These premature bearing-down pains may often be mitigated by a recumbent posture and the use of a mild clyster to empty the rectum. In some cases the womb prolapses so that its mouth appears at the orifice of the vagina.... It is often met with in a slight degree whilst the os uteri is not greatly dilated, and often injures the labour.

We are to prevent it from increasing by supporting the head or uterus with two fingers during the continuance of a pain" (Burns is ignorant that during labour the head of the infant is passive, and that the uterus is the active agent), "at the same time

that the woman avoid as much as possible any bearing down effort, and remains in a recumbent posture. If the os uteri be slow of dilating, some blood should be taken away, and an opiate administered, or the os uteri gently but completely dilated during successive pains." Such is Dr. B.'s description of, and treatment for, a case of tedious labour, in which the cervix is interposed between the head of the infant and bones of the pelvis; but he not only makes no allusion to the important fact that the cervix must thereby be intercepted, but his treatment is precisely the same as what he recommends for ordinary cases of tedious labour, with the exception of supporting the head or uterus with two fingers during a pain, to prevent the further descent of the uterus. If Dr. H. consider this a case of interception, it is clear that his rebuke upon this latter mode of treatment applies much more to Dr. B. than to me, who meant by interception of the cervix a totally different case. There are cases in which, whether from anterior obliquity of the uterus, or the promontory of the sacrum projecting too much in an otherwise wide pelvis, or that the axis of the brim approaches too near the horizontal line, the direction of the uterine force is not in the line of axis of the brim; if the membranes are prematurely broken, the pains press the head strongly against the pubic margin during the dilatation of the os tincæ, and thus intercepts the anterior lip; consequently, while the remainder of the dilatation advances more or less rapidly, this portion is arrested; if the interception continues, it becomes tumid, painful, and ultimately inflamed; in some instances it has terminated in laceration of the part. To obviate such effects, some have advised pressure against the head during a pain, as well to remove the compression from the anterior lip as to aid in giving the head its proper direction towards the cavity of the pelvis; others prefer endeavouring to press the lip itself upwards, so as if possible to slip it over the head, and above the point of compression, but which attempt, excepting in a very wide pelvis, where the head can pass down along the fingers, produces exactly the same effect in pressing the head upwards. The management of either case presupposes the existence of active labour forcing the head down upon the pubis. It was to such interception I alluded when I stated that Dr. H. seized upon the fact "that a portion of the os tincæ still covered the head of the child," to attribute the delay to interception of the cervix *. And in the same sense, replying to Dr. H.'s accusation, that "in this shockingly misina-

naged case, instead of assisting the dilatation, an opiate was given," I used the words which Dr. H. has had so much difficulty in finding gentlemanly language to repel. "In order to make this (the above) objection intelligible, he (Dr. H.) asserts the cause of delay to be intercep-tion (not interposition) of the cervix uteri, though at no period of the labour did the pains become expulsive, and throughout the uterus acted imperfectly; the head, therefore, could not have been (low in the pelvis? no, but) forced down upon the pubis so as to intercept the cervix." Upon which Dr. H. makes the following lucid remark:—"From this sentence, it is evident that Dr. M. believes that the uterus cannot be interposed between the head of the infant and the bones of the pelvis, without there having been expulsive uterine contractions!" At the same time that I give this explanation of the meaning of the term I had used, and one I believe quite in accordance with the principles of midwifery, I mean not to deny that partial prolapsus of the uterus may be accompanied with interception of the cervix, but then there must be some evidence of it; the os tinæ would not be described as being "lax and thin," or that "all that seemed wanting was, that the pains should become expulsive," in order to effect the delivery. The only fact in the case before us which would at all countenance such a supposition in the absence of every other evidence, is the very one which Dr. H. has taken so much pains to conceal—viz., the great difficulty of extracting the head with the crotchet; and I freely give Dr. H. all the advantage he can make for himself out of the admission. The next point I have to consider in the way of digression is another charge of misrepresentation. In order to demonstrate, in the clearest manner, the propriety of suspending inefficient uterine action by an opiate, in preference to fruitless and harassing attempts "to assist the dilatation," I quoted a passage from Dr. H.'s work. To this Dr. H. has objected, and refers his reader to page 89 of his Practical Observations, pt. II, for his real meaning, "in which (says Dr. H.) he will find a very different rule for the exhibition of opiates." The passage is as follows:—"The safety and utility of opiates must be very carefully considered before being prescribed. If there be pain in the head, or any circumstance whatever which might render the further protraction of labour for ten or twelve hours injurious, opiates are most dangerous." The very next sentence is that which had been quoted: "*The only utility of opiates in cases of protracted labour, is to suspend inefficient uterine contractions, which wear out the strength of the*

patient, and there are no marks by which the one result or the other can be calculated upon." Now, I would ask the reader, when the entire of this passage is applied to a case in which I especially dwelt upon, "the inefficient uterine contractions" as being its most prominent feature, and that an opiate was given on the first and only evidence that "they were wearing out the strength of the patient," whether I was not justified in quoting Dr. H. authority. "It is to be noted" that the woman was 60 hours, not several days, in real labour; and that the opiate was given on the first indication of exhaustion. That it failed in its effect may be attributed to a cause which I dwelt upon at length in my former paper.

The next evidence of ignorance is contained in the following words:—"It must also strike the intelligent practitioner that the forceps employed for an hour and a half compressing *such a head* would be a very likely way to produce such an effect (suspended animation); besides, it is not probable that the forceps could be applied without moving the head from its position, and still less that some meconium would not have escaped if at all pushed back, had the child been previously in danger."

From this passage Dr. H. infers my ignorance. "1st. That during the interval of working, the pressure of the instrument upon the head of the infant is to be removed. Compression of the head of the infant by means of the forceps for an hour and a half was never heard of in this part of the world. 2dly. As to the head being moved from its position by the application of the forceps, that is an effect of the application of the instrument totally unknown here." In Dr. H.'s case, "even a bungling operator could not have moved the head from its position, for the record bears (what is the *real truth*) that the head completely filled the pelvis. 3dly. My ignorance that the head of the infant can safely be diminished by approximating the parietal bones." The answer to the first of these deductions would strike any one but Dr. H. How could the pressure of the instrument in the interval of working be removed from a head which even the most bungling operator could not stir from its position? But my meaning in the above passage referred to the compression kept up *during the pains*, for an hour and a half, for the purpose of diminishing the bulk of the child's head. As to the second statement, had Dr. H. confined himself to his own experience it might be intelligible; but when he states, "that moving the head from its position by the application of the forceps, is an effect totally unknown here," I cannot permit such an imputa-

tion upon the practitioners of Scotland to pass without a plain contradiction. On this point I again avail myself of Dr. B.'s authority, from whom, though I differ essentially on some points of practice, I still can appreciate as a valuable writer; to his work, therefore, I refer, as being a text-book of the principles of midwifery—as being decisive evidence what those principles are on Dr. H.'s side of the channel—and especially as being an advocate for the use of the forceps, as nearly approaching to the doctrines of Dr. H. as a rational practitioner could venture to adopt. Burns, speaking of the application of the forceps in cases of impaction, observes, "When we talk of a case of impaction, which is not a very happy term, we must not, however, suppose that the head is *literally and entirely immovable*. That it is, in the strict sense of the word, sometimes impacted and cannot be recovered is no doubt true; but this is not a case in which we can safely use the forceps, more frequently the hand can make it recede a little, although the uterus cannot make it advance any more." Then having alluded to Levret's opinion, he proceeds, "Røderer went further, and maintained that every part of the head was so fixed and pressed on, that not even a needle could be passed any where between it and the pelvis. *If so, how could the forceps be applied?* If the head be jammed at every point, even making allowance for the elasticity of its bones, we could not introduce the finger between it and the pelvis, and reach the ear (an object not sought for by Dr. H.) The impacted head, admitting the use of the forceps, is stopped by the promontory of the sacrum on the one hand, and part of the pubis on the other; the resisting point is generally the projection of the sacrum; but even in this case the term impaction is not strictly proper, *for if the forceps can be used the head can be a little raised*, and the blades must be capable of being introduced*." Such are Dr. B.'s directions for the use of the forceps, under circumstances in which it is still a question at issue whether it should be used at all. Dr. Campbell (another authority on the principles of midwifery in Scotland,) says, "It is scarcely necessary to state that impacted head, except when detected early, can rarely be referred to the present order (where the forceps may be used), since an attempt to elevate it in the pelvis, with a view to apply some mechanical power (lever or forceps) to accomplish its extraction, may, on the one hand, be attended with laceration of the uterus, and on the other with contusion of the pelvic linings†." Both writers thus assume the

necessity of moving the head from its position, in order to apply the forceps, and therefore give a direct negative to the assertion, that "the head being moved from its position by the application of the forceps is an effect of the application of the instrument totally unknown here" (Scotland.)

The third inference refers to Dr. H.'s asserted power of the forceps, by which he states that the head can be diminished from three and a half to three inches between the parietal protuberances*, and therefore may safely be applied to such cases as have been described, viz. where the infant is wedged in the passage. To its power and application, under such circumstances, I objected, and referred to Bandelocque's experiments on still-born children, in which the strongest French forceps were used to compress the head, with such force that one of them was bent, and even this only reduced the head twenths. I therefore inferred, that when such was the result with the French forceps on a dead child, the degree of diminution caused by the English forceps on a living infant must be very trifling, independently of the hazard of using so much force.

Dr. H.'s commentary on this note is as much to the point as many other of his observations. He assures the reader I was "forgetting that each blade of Bandelocque's forceps is nearly a quarter of an inch thick," and therefore one would suppose the more difficult to bend, and a more decisive proof of the enormous power used to accomplish so trifling a diminution.

On this point, also, I refer to Dr. Burns, who states, "The forceps, as I have ascertained by experiments on recent foetuses, cannot diminish the lateral diameter above a quarter or at most three-eighths of an inch without altering the shape of the bone itself, that is, fracturing it;" and after a discussion on its use in the cases alluded to, concludes, "The truth is, that this instrument is not proper when much resistance is to be overcome, or when the pelvis is barely sufficient to allow, with great exertion, the head to be brought through. We may at last succeed, but the child is killed, and the soft parts of the mother inflame and slough, or she is exhausted and dies†." In the same manner Dr. Campbell, speaking of labours of this description, observes, "If the foetus be at the full time, and of the ordinary size, we can neither accomplish its extraction successfully by mechanical invention, nor can we expect that the expulsion will be effected by the natural efforts, unless there be a clear space of three inches and one

* Burns' Principles, p. 465-6.

* Hamilton, p. 112, Part ii.

† Burns' Principles, p. 474-5.

half between sacrum and pubes, and the same betwixt the tuberosities of the ischia." This statement, I am aware, is at variance with the sentiments of some veteran practitioners, who think they have succeeded in extracting living infants by a mechanical power immediately to be considered (the forceps) through pelves of only three inches short diameter at the brim*. Who the veteran practitioners may be to whom Dr. C. alludes, I shall not undertake to say. But it is clear that one veteran at least has been labouring under such a delusion, and also that his powers in this respect receive no support, even from Caledonian authorities on the principles of midwifery. Were I to add to these other authorities, whose opinions have become a standard of those principles, and who are much further removed from an admission of those doctrines than those whom I have quoted, a clearer proof would be afforded that Dr. H. stands alone in his opinion; and it will be, perhaps, granted, that when Dr. H. brings forward such topics as proofs of my ignorance of those principles, the professor himself requires some little information on the subject. To Dr. H.'s explanation—why I have found his language ambiguous, I have only to give a ready assent "Language may be ambiguous to the reader or hearer, in consequence of their own ignorance." And as I happen not to know, that when the cervix uteri is interposed between the head and pelvis, it must be intercepted, that when the head is immovably wedged in the pelvis, it can be delivered by the forceps with perfect security to mother and child, and that it can safely be compressed within a less space than Baudelocque or Burns' could effect with all their force on still-born children, it is evident. "I cannot be expected to understand the practical precepts of Dr. H.," which can only be intelligible to those who have the good fortune to be "properly educated" in such valuable doctrines.

Having already examined at length Dr. H.'s proofs of the dangerous tendency of our modes of practice, to which Dr. H. has given no better reply than that which I am now obliged to notice, it will not be necessary for me at present to do more than to demonstrate how completely incapable Dr. H. appears to be of reasoning fairly on the subject. The first proof Dr. H. has given of the dangerous tendency of one precept, viz.—"That artificial assistance (the crotchet) was never attempted until the safety of the patients required it," is "the appalling fact," which has been already exposed, and when no better evidence is given than a false statement,

it is not necessary to undertake any defence of it. The second proof is in reply to my assertion, "That it has been proved, as Dr. Collins observes, that when the patient has been properly treated from the commencement of her labour, the death of the child takes place in laborious and difficult labours before the symptoms become so alarming as to cause any experienced physician to lessen the head." "It is here asserted (says Dr. H.) that it is proved that when the woman had been properly treated, the death of the infant *always* takes place before symptoms of danger occur." The reader will perceive Dr. H.'s interpolation of the word "*always*," the better to bring forward these cases, all given and considered before. I shall not now again examine them, but merely observe that I have not yet been able to find a proposition in medicine *always* true. The truth or falsehood, therefore, of the cases Dr. H. again details cannot overturn the truth of a proposition founded upon the whole number recorded. Dr. H. has carefully avoided taking the whole of Dr. Collins' report as a basis in the discussion of these questions, and until he does so it is needless to say it is unfair to argue on cases which at most may be but exceptions. Dr. H.'s mode of dealing even with these cases has been fully discussed; but if an additional evidence were required of Dr. H.'s inconclusive proofs, and of the spirit in which they are given, I need only quote the following passage:—"Dangerous as the preceding precepts are, the third proposition advocated by Dr. M., while it is equally calculated to mislead the junior members of the profession, is so preposterous, that if Dr. M.'s own words could not be brought forward to prove it, no individual who had been taught the elements of midwifery (by a competent teacher) could have hazarded it." What is the preposterous precept? Is it to endeavour with the forceps to drag the child's head through a pelvis in which it cannot be stirred? No—"but that no practitioner is justified in destroying a living infant without his having sufficient evidence to prove it actually necessary, as that necessity must arise from actual danger to the mother, so the evidence must be positive, not imaginary, or, in other words, must depend upon the presence of dangerous symptoms to the mother, not upon the conviction that they would have presented themselves had not the child been destroyed." "Reasoning with such a person (says Dr. H.) is a hopeless task, and therefore Dr. H. presents the reader with the following recorded case, as completely shewing the effect of adopting the precept under consideration." The case quoted is an arm presentation in a pelvis, 2½

* Campbell's System of Midwifery, p. 229.

inches in ant.-posterior diameter, which in the early part of the labour was mistaken for the knee; and in six hours after, when the elbow was detected, the body was so wedged in the pelvis as to render it impossible to turn. Perforation of the thorax was had recourse to, which was accomplished with extreme difficulty, and the cervix uteri was lacerated. Dr. H. has thus the gratification of quoting another bad case, equally embarrassing as unfortunate in the result, and one in which the difficulties were greatly increased by the error committed in ascertaining the presentation. But what does it prove against the precept quoted? Nothing whatever, unless it be assumed that an arm presentation is not a symptom of actual danger to the mother, or that a pelvis $2\frac{1}{2}$ inches in diameter is not positive evidence that delivery is necessary; but as the presence of either or both places the certainty of danger to the mother beyond doubt. This case only proves the rule, for when the safety of the woman required it, the child was destroyed.

The passage quoted was an argument I had advanced to prove the utility of the stethoscope in those cases of difficult labour, wherein the existing disproportion could only be ascertained by the progress and effects of the labour; and in opposition to Dr. H.'s very mischievous assertion, "that it is in the power of the practitioner to foresee and prevent the occurrence of injury," by delivering in such doubtless cases. I denied that any practitioner was justified in destroying a living child on *convictions* so acquired, without having the positive support that dangerous symptoms to the mother were presenting themselves. But Dr. H. takes an extreme case in which symptoms of danger were in existence from the beginning, and which would authorize the destruction of the child if necessary when such symptoms were known; but because a delay arose from an accidental cause, which prevented a more timely interference, Dr. H. quotes it "as a case most strikingly illustrative of the dangerous tendency of three practical precepts," which have no reference whatever to such cases. When such is the illustration of Dr. H.'s argument, it is easy to understand why reasoning has become "a hopeless task."

The last topic which I have to notice is Dr. H.'s defence of his manner of quoting Dr. C.'s cases. He quotes my objections thus:—"He (Dr. M.) begins by saying, page 423, that Dr. H. may have supposed that because the cases he has been pleased to select are not incorrectly quoted there can be no cause of complaint; but in some of them, he has obviously misunder-

stood the details. The omission of the disproportion in one case (2.), we have seen is enough to furnish Dr. H. with an argument. Similar instances occur in other cases; for instance, where the treatment is not mentioned, he assumes it not to be adopted; though Dr. C. quite sufficiently explains what the general treatment was; nay, on the strength of the omission, Dr. H. endeavours to make the practice contradict the precept." Having quoted this, and another passage nearly similar, in which it was shewn that the omissions of one case, the ambiguity of another, the misconception of a third, formed the ground-work of Dr. H.'s commentaries, Dr. H. bursts into an exclamation of most dignified surprise. "Much as Dr. H. has had occasion, in his professional capacity, to point out the inaccuracy of reasoning in medical authors, he fairly owns that he has seldom met with any thing like the remarks in the foregoing quotation.

"Firstly, it is asserted that quoting cases correctly does not exclude complaint on the part of the author; secondly, that some errors in sense, if in opposition to the practice stated in the text, should raise a doubt as to the accuracy of the details of the cases; thirdly, that the omission of one case, and the ambiguity of another, and the misconception (Dr. H.'s)* of a third, being most palpable mistakes, should have been understood and corrected by Dr. H. Now when the reader is informed that it is expressly stated in the section from which these cases are taken, that they are curtailed, the statement, he will allow, implies that there must be omissions, and if these omissions (as of treatment) had been previously explained in the text, there could be no very great difficulty "in understanding the practice adopted." But if the case is made to contradict the text, on the strength of the omission alone, it must give false evidence. In the same way an ambiguity might arise from sentences being abruptly juxtaposed, which would lead to error in the reading of it.

When, therefore, 49 cases were compressed into 23 pages, some of them consisting of only a few lines, any one but Dr. H. would have assumed with regard to them such points as had been previously stated. He would not, for instance, take a case† from amongst a number of cases

* Dr. H. says "misconception in a third."

† Dr. H. says "It is impossible to imagine a more disingenuous allegation than that of Dr. Murphy, in asserting that there had been a disproportion in this case which had been omitted. If there had really been a disproportion it was unjustifiable to allow the infant's head to make no progress for the last 24 hours." Justifiable or otherwise, the fact of the infant's head being stationary is rather a novel proof that there was no disproportion.

of extremely severe labour in consequence of disproportion, and assert that there was no disproportion because it happened not to be stated in the case. Neither could he assume that the cases were neglected, because the treatment previously mentioned was not detailed in every case; yet such have been the means by which Dr. H. has brought these cases in evidence against the work itself. Dr. H. has expressed much astonishment in being required to supply an omission; he seems to find it easier to omit what has been supplied. The first passage of mine above quoted has been completely garbled: between the two sentences "there can be no cause of complaint"—"but in some of them he has obviously misunderstood the details," there are just fourteen lines of explanation, which Dr. H., finding it a hopeless task to answer, has left out without even acknowledging the breach. As the omitted passage conveys the force of my objection, it is fair to repeat it here:—"Dr. H. may have supposed that because the cases he has been pleased to select are not incorrectly quoted, there can be no cause of complaint, but when it is considered, that these cases are quoted to prove general assertions as to the practice adopted in the lying-in hospitals—that they are taken from a mass of facts of the most opposite kind, in which every particular which could assist the reader in ascertaining the proper value of each, is given with unusual minuteness—that to the exclusion of every other, the most unfavourable cases are selected by Dr. H., and upon their evidence a judgement passed upon the whole—it will be admitted, perhaps, that such a mode of treating a report is not a fair representation of the facts and practice contained in it. But Dr. H. has not only thus misrepresented the results of Dr. Collins' practice, and failed to establish the utility and importance of the precepts by the cases which he has given, but in some of them he has obviously misunderstood the details*," &c. I had there pointed out the different cases misinterpreted by Dr. H., but in place of meeting me upon them, he affects to wonder he should be required "to correct the sense" (there were no errors in sense but those created by Dr. H.) "to supply the omissions," and "to clear the ambiguity of the record.—Presuming (says Dr. H.) as a matter of course that Dr. Hamilton, being a native Caledonian, must have the second sight." When Dr. H. has been so completely blind to what must be obvious to every one, the weakness of his position, and the manner in which he has exposed him it, I should be the last to attribute to

this remarkable attribute of national foresight.

It requires, however, no second sight to see that Dr. H. has not been able to meet the objections made to the manner in which these cases are quoted.

Having thus noticed the principal assertions and charges contained in Dr. H.'s "Observations," I cannot conclude, without again expressing the reluctance with which I have been drawn into a line of disputation equally useless to the inquiring reader as uncongenial to my habits. For the purpose of divesting a very interesting subject of inquiry of much irrelevant matter I had examined Dr. H.'s letters as dispassionately as it was in my power, and while I pointed out Dr. H.'s errors in reasoning, and the mistakes into which he had been led, I avoided the use of any language which could be considered as personally disrespectful to him; nevertheless, in self-defence, I have now been compelled to expose traits in Dr. H.'s character as an author which I would gladly have avoided.

Dr. H. has denied having invited a controversy; I could not but give a history of facts. He has accused me of "flagrant misrepresentations;" I have been obliged to expose the flagrant misrepresentation on which the accusation was founded. He has charged me with ignorance of the principles of midwifery; I am constrained to quote conclusive evidence to prove that Dr. H. seems unacquainted with any principles but those dogmas which he has been labouring for years to impress on the profession, and which, being constantly repeated with all the confidence of acknowledged truths, have been mistaken by Dr. H. for such. The very same "proofs" as before, of Dr. C.'s and my "dangerous precepts," are again brought forward, only a little varied, and one new one added. Dr. H. having passed over the objections offered to these cases being considered proofs, it only remained for me to shew, what indeed the last case brought forward sufficiently proves, that Dr. H. does not seem to know what a proof really means. Thus I have been obliged to bring before the notice of the profession points which I would willingly have suffered to rest in oblivion.

Under these circumstances it is hardly necessary to add that, when Dr. H. has mistaken so completely assertion for proof, vituperation for argument, it is needless to prolong a useless discussion. Dr. H. has expressed his intentions in this respect hypothetically; and as time has had little effect with him in diminishing a taste for disputation—as we cannot say of him

"*Lenit albescens animos capillus
Litium et sisæ cupidos protervæ;*"

and as he has given so many "decided proofs" of

— "the skill,

By which, tho' conquered, he can argue still,"

it is quite possible he may think that the proofs of his propositions have not "been made out to the satisfaction of the reader" sufficiently "to exonerate him from noticing any article which may in

future appear under the signature of Dr. Murphy." I can only say, should such be the case, I shall leave to Dr. H. the undisturbed privilege of concluding the controversy.—I am, sir,

Your obedient servant,

EDWARD WILLIAM MURPHY.

LECTURES
ON THE
CHEMICAL HISTORY, PATHOLOGY, AND
MEDICAL TREATMENT

OF
CALCULUS,

AND THE VARIOUS DISORDERS OF THE
URINARY SYSTEM.

By DR. VENABLES.

Xanthic oxide calculus.—This species, as already stated, is but of rare occurrence, and has, as yet, been but once unequivocally demonstrated in this country. But Professor Langenbeck, of Göttingen, extracted a stone from the bladder which, on analysis, was found to consist of xanthic oxide. Its analysis also proved that its chemical composition was exactly identical—minus one equivalent of oxygen with that of lithic acid; and therefore it was named *lithic oxide*: and the properties which it possesses completely verify a former proposition, that the quantum even of a single material often proves sufficient to modify the characters of a compound, and to produce truly distinctive phenomena. Thus the abstraction of a single atom of oxygen from the lithic acid would give the chemical composition and modified characters of xanthic oxide. The properties, as enumerated by Dr. Marcet, are as follows:—

1. When entire, it was of an oblong or spheroidal shape: weight about eight grains.

2. Texture compact, hard, and laminated; surface smooth; colour that of cinnamon, which was much deepened by the addition of caustic alkali. Between

the red laminae, faintish white lines were perceived.

3. Before the blow-pipe, it crackled, split into small pieces, turned black, and was ultimately consumed, leaving a minute white ash. During the dissipation, a peculiar animal odour, feeble, nor easily defined, was given off. This odour did not resemble that of either the lithic acid nor cystic oxide.

4. Exposed to destructive distillation, it crackled, blackened, split into scaly fragments, emitted a foetid ammoniacal liquor, from which, on cooling, carbonate of ammonia crystallized, and a heavy yellowish oil separated.

5. Reduced to an impalpable powder, and boiled in water, it was nearly wholly dissolved, and the solution slightly reddened litmus paper. The clear liquor, decanted and allowed to cool, became covered with a white flocculent film, not crystalline, but which gradually subsided, forming a white incrustation; and the vessel being scratched with a pointed instrument, just before the deposition took place, white lines appeared at the point of contact; as in the case of the ammonio-phosphate of magnesia.

6. It dissolved readily in caustic potash, from which it was precipitated by acetic acid, if not in very great excess. It was also soluble in ammonia and the alkaline carbonates*.

7. The mineral acids dissolved it, though not near so readily as the alkalis; and hence Dr. Marcet presumes, or rather suggests, whether the solvent agency of the acids may not depend upon their water: consequently the *anhydrous* acids would not dissolve this calculus.

8. The residues of its solution in the hydrochloric and sulphuric acids were white; and so far as could be observed from the limited experiments which the

* Named by Dr. Marcet, "*sub-carbonates*."

minute portions of the calculus that could be devoted to this purpose admitted, no distinct crystals were formed. Concentrated sulphuric acid did not blacken it.

9. Its solution in nitric acid evaporated to dryness left a residuum of a bright lemon colour. This yellow residue was partly soluble in water, to which it communicated its colour. The addition of an acid took away the yellowness; but the addition of caustic potass immediately turned it to a red colour, more or less intense in proportion to the degree of dilution; and which, upon evaporation, assumed a brilliant crimson hue, which, however, disappeared on adding water, the yellow colour being restored, and remaining perfectly transparent. The previous action of the nitric acid is necessary for the development of these singular properties; for when potass was added to the pure calculous substance, such as deposited by water, no change of colour took place. The residue of the solution of the calculus in water, treated with nitric acid, produced the yellow substance equally the same as the calculus itself.

10. It is insoluble in alcohol or ether.

11. It is but very sparingly soluble in acetic acid.

12. It is insoluble, or nearly so, in oxalic acid.

13. It seems to be insoluble, or nearly so, in bicarbonate of potass, or saturated carbonate of ammonia.

Distinguishing chemical characters.—This substance, Dr. Marcet observes, is entitled to be considered one *sui generis*, and probably hereafter will prove to be an oxide (a suggestion which recent discoveries have fully confirmed), though he states it is much less soluble in acids than the cystic oxide. The only substances with which it could well be confounded are the lithic acid and cystic oxide. The rarity of the substance prevents offering any distinguishing characters before the blow-pipe; though Dr. Marcet states the odour to be peculiar, and very distinct from that of the other two. Yet there are other chemical characters sufficiently obvious, and perhaps much more characteristic. From lithic acid it may be distinguished by its comparatively much greater solubility in water, and by the lemon yellow colour given to the residue from its digestion in nitric acid.

From the cystic calculus it may be distinguished, inasmuch as cystic oxide evaporated from its solution in nitric acid leaves a white residue; has a smell peculiar to itself; is not laminated; is rather more soluble in alkalies, and much more extensively so in acids, than the xanthic calculus.

In fixing upon a name for this calculus,

Dr. Marcet was entirely guided by the action of nitric acid, as already stated, producing a yellow colour; hence he named it "*xanthic*," from the Greek word *ξανθος*, which signifies *yellow*; and therefore as this epithet reminds us of a striking, invariable, and, in all probability, a *unique* and characteristic property, it seems so far unobjectionable.

Fibrinous calculus.—We are also indebted to Dr. Marcet for the chemical description of this calculus. It was sent to Dr. Marcet by Sir Asley Cooper, with the inquiry, "Is it cystic or uric?" It was about the size of a pea; and after a slight examination Dr. Marcet perceived that it did not belong to either species. Upon submitting it to the proper investigation, it was found to possess the following properties:—

1. It had a yellowish brown colour, resembling bees' wax, and nearly about an equal degree of hardness and consistence. The surface was uneven, but not rough; texture fibrous rather than stratified, and the fibres seemingly radiated from the centre. It was somewhat elastic.

2. Exposed to the flame of the spirit-lamp it took fire, swelled out, blackened, and ultimately passed into a light spongy carbonaceous mass. During combustion it emitted an animal odour, in no way resembling that from the lithic, the cystic, or the xanthic calculus.

3. It was insoluble in water and in hydrochloric acid; but, boiled with caustic alkali, it formed a soapy solution, from which the calculus was precipitated by hydrochloric acid.

4. Nitric acid dissolved it, though much less readily than the lithic or cystic calculus; the solution on evaporation to dryness did not produce any red or yellow stain.

5. Boiled in very dilute acetic acid it first swelled to a greater size, but was at last dissolved. On adding to this solution prussiate of potass—ferrocyanide of potassium—a yellowish precipitate was thrown down. Now the above properties are such as, we have already shewn, principally distinguish fibrin; consequently calculi of this description may properly be named *fibrinous*. It is unnecessary to consider the chemical habitudes of this species more at length.

Prostatic calculus.—Calcareous concretions are sometimes formed in this gland, and these occasionally produce symptoms very closely resembling those of stone in the bladder. Their appearance, too, if any be voided, is often so like that of lithic concretions, that unless their nature be determined chemically, they will be readily mistaken for that species. It is to Dr. Wollaston that we owe our knowledge of

the true composition of these substances. They consist of the phosphate of lime, not distinctly stratified, and tinged more or less by the secretion from the gland; they consist of neutral phosphate, without any excess of base, as in the case of bones. In size they vary from that of a pin's head to that of a hazel-nut. There also seems to be two varieties of them: the first is formed in the natural cavities of the gland, before it becomes much disorganized. Generally speaking they are small, more or less spheroidal or rounded in shape, and are of a yellowish brown colour. Here are some specimens. In this drawing, fig. 2, plate ix. of Marcet's work, you have a representation of a section of a diseased prostate, the enlarged cells of which are occupied by calculi of this description. The second variety is found mostly in abscesses of the gland, and often in very great numbers. They present a porcelainous or highly-polished appearance, and are much larger in size than the first variety. Here are a few; and fig. 1 of the plate I have just shewn you gives a view of this form of diseased prostate. In this drawing the calculi appear as if enclosed in a cyst, formed in the right lobe of the gland, and which is much enlarged. In composition, however, both varieties are essentially the same, namely, they consist of phosphate of lime; and as this substance does not seem to be ever deposited in an unmixed state by the urine, prostatic calculi can always be readily distinguished from urinary ones.

Chemical characters.—The first variety are those which are most likely to be mistaken for the lithic species. Before the blow-pipe the phosphate of lime suffers no change, whereas the lithic calculus dissipates, and leaves a minute alkaline ash. The phosphatic residue exhibits neither acidulous nor alkaline reactions, when tried by test papers. The phosphate, if mixed with ammonio-magnesian phosphate, fuses; the lithic calculus suffers no changes whatever of this sort. Acted on by nitric acid, the lithic acid suffers specific and characteristic changes; the phosphate merely dissolves, and is recoverable, unaltered either by dissipating the acid by evaporation or by neutralization and precipitation. Lastly, the characters detailed in a former lecture will identify the composition on submitting it to the processes already described, and which it is unnecessary here to repeat.

Silicious gravel.—We have now considered the principal urinary calculi with a view to their chemical identification, and what has been stated of these will equally apply to the other forms or modes of the same compounds; and the gravelly and amorphous sediments may be chemically identi-

fied by the same means. It now remains that I bring before you a singular species of gravel, which, though frequently announced, had never been unequivocally detected till I met with an instance which, though attempted to be disputed as a case of imposition, yet am I so fully satisfied, that, with the precautions adopted—adopted too under a thorough conviction and the fullest impression of the great probability of such an attempt—I cannot doubt for a moment that the specimens I now send round are really and *bond fide* of urinary origin. These, when first passed, had a slight coating of lithic acid; and indeed I mistook them for minute granules of this substance; but acting upon them with nitric acid I was surprised to see that they completely resisted the solvent powers of this fluid. I found that they became crystalline grains, resisting the mineral acids, and even the action of the alkalis. The blow-pipe had no effect, unless aided by potass or soda, when they fused and melted before the instrument. They resisted every reagent but the hydrofluoric acid; and they were so hard as to scratch glass. These properties induced me to believe that the granules were truly silicious; and shewing some to Dr. Prout, he pronounced them silicious, but could not bring himself to believe in their urinary origin. I, however, felt so satisfied, that I determined to make public the facts, with the view rather of exciting attention than any impression of communicating any thing of very great value. A paper detailing the particulars of the case, and to which I refer you, was sent to the Journal of the Royal Institution. While it was in the press, and I believe before publication, Dr. Yelloly, who was at that time engaged in examining the calculi in the Norwich collection, met with an oxalate of lime calculus which exhibited some anomalous characters; and, in consequence, he brought it to the Royal Institution, to Mr. Brande, who, on examination, found some small granules embedded in the interior substance of the oxalate to consist of silex. Dr. Yelloly was apprised of my communication, and wrote to me for some of the specimens, to compare with those which he had discovered, and I sent him those which I now present for your inspection. The doctor, in a paper read before the Royal Society, and which has been published in the Philosophical Transactions, has contrasted the general appearances and properties of these two; and I think, if you will refer to the paper as above, you will find the analogies sufficient to justify the conclusion of the similarity of their origin.

Now I think there can be no question of the urinary origin of the silex found em-

bedded in the interior of the oxalate of lime, because it is not otherwise easy to conceive how they could have got enveloped in the calcareous deposit, unless they had separated from the urine at the same time, and been deposited with it; but the oxalate being found in much greater quantity, speedily encrusted the granules, and at last deeply covered them. If, therefore, the case brought forward by Dr. Yelloly justifies the conclusion of such an occurrence, there can be no longer any reason to doubt of the occasional deposition or separation of silicious matter from the urine; and probably when this excretion comes to be more closely attended to, perhaps instances of the above description will not be quite so solitary.

With respect to the chemical characters, they no doubt are by this time sufficiently well understood. If they resist the blow-pipe, resist the action of nitric acid, but melt into a glass with soda or potass before the blow-pipe, there can be no doubt of the nature of such gravel*.

Symptoms of stone.—As calculi are formed by the aggregation and consolidation of the saline matters usually existing in solution in the urine, it is evident that they may form in any part of the urinary apparatus where this fluid, lodged or passing through, can no longer hold these principles in solution. Hence calculi may be, and often are, found in the pelvis of the kidneys, in the ureters, in the bladder, and even in the urethra. The circumstances which dispose them to form in one situation rather than another, are various, and depend upon causes differing in different cases.

Stone in the kidneys.—The formation of stone commences in the kidneys more frequently than in any other situation. The urine secreted by the minute ramifications of the renal arteries passes into the infundibula, through which it slowly percolates into the pelvis, from which it passes into the ureter, to be ultimately transmitted through this tube into the bladder. If, during its transmission or filtration into the pelvis, it should be so loaded with calculous matter, or the urine be altered to a state incapable of holding it in solution, of course it will be deposited, and give rise to a calculous concretion. Sometimes concretions even are found in the infundibula themselves, and they sometimes stop in the pelvis, either forming in great numbers, or one greatly increasing in size, and distending the pelvis into an enormous pouch, and producing a wasting or ab-

sorption of the glandular portion of the kidney. I here shew you several which were taken from the pelvis after death. In this plate also, No. 1 of Dr. Marcet's work, not only are the calculi seen in the pelvis, which is much enlarged and distended, but even the infundibula are enlarged and distended by calculous accretions, while the substance of the kidney has been gradually and proportionally absorbed. The calculi which are seen in the pelvis, it may be supposed, form some peculiar morbid condition of the organ, as well as from their own rapid growth, instead of being expelled, are retained immediately on their formation, become blocked up there, and, still continuing to increase, produced the appearances delineated in the plate.

Sometimes, instead of several smaller calculi, a single mass of calculous matter is found in the pelvis; and, as in plate 11, which I shew you, the calculus becomes moulded by the walls of the pelvis, so as resemble a cast of this bag and its ramifications. As the bulk increased, the texture of the kidney became altered in such a manner as to leave nothing but a sort of pouch or cyst, wholly occupied by the calculous mass which occasioned these effects in the manner depicted in the plate.

Stone in the ureters.—Calculi are also sometimes found in the ureters, and most frequently in the upper portion of these conduits, where they are much expanded, resembling a sort of funnel. When calculous matter is disposed to be deposited, the first portion deposited is prevented passing by the gradually decreasing calibre of the ureter, and being detained, gradually increases in size. I here shew you a curious little calculus of lithic acid, and which, from the history and appearance, we may presume was gradually formed in the ureter. You observe it is long and round, forming a sort of roundish cone, somewhat like the small pestles of agate mortars. It is small, and pointed at the apex, gradually enlarging till we come to the base. Now this is somewhat the shape of the ureter as it approaches the pelvis: it proceeds narrow from the bladder, but, as it approaches the pelvis, it dilates gradually, till at last it expands into the large cavity, named as above. Now this little calculus no doubt lay in the ureter, with the apex towards the bladder, and the base of the cone towards the pelvis, and, by the urine and some accidental circumstance still further favouring, was at last carried into the bladder. It does not appear from the history, nor even from its appearance, to have long remained in this situation. The patient (a boy) found that he experienced suddenly some difficulty in passing his urine, which gradually increased, till

* For fuller and more specific details I refer you to the *Journal of the Royal Institution*, and to Dr. Yelloly's paper in the *Philosophical Transactions*.

at last he could scarcely pass any. He was supposed to be suffering from stricture; but one or two attempts to pass a bougie were unsuccessful, when one morning his medical attendant, on examining the urethra, thought he perceived something in the passage, and which he endeavoured to lay hold of with a forceps. After a great deal of difficulty he succeeded in extracting the lithic calculus which I have shewn you, and which, from its length and round shape, you must observe, received its moulding in some canal, and this, no doubt, was the ureter. This is the account which I received from the gentleman who extracted it, and gave it to me. I may here observe, that if the penis had been sufficiently examined by the fingers externally, that portion of the urethra in which the calculus was lodged would have presented a hard and resisting feeling to the touch, while all the other portion would have been of its natural feeling; and thus some clue might have been obtained as to the nature of the case.

LECTURES

ON THE

VENEREAL DISEASE,

Delivered at the Aldersgate School of Medicine,
March 1839,

By F. C. SKEY, F.R.S. &c.

LECTURE III.

Eccentric Actions of the Phagedænic Sore—Primary Phagedæna of questionable existence—Phagedænic Disease of spontaneous origin in certain constitutions—Character of Phagedænic Action—Is Slough or Pus the product?—Three Forms of Phagedænic Sores—Bubo—Phagedænic Secondary Disease—Eruptions, Sore Throat, &c.—The Phagedænic Scaly Eruption—Mercury competent to develop Phagedænic Disease independently of Venereal Disease.

ON THE PHAGEDÆNIC ULCER.

THIS is by far the most important form of sore we are called to treat—on the ground of its frequency, its destructive actions, and its intractability by treatment. It is not necessarily a venereal sore, although its origin may be occasionally referred to sexual intercourse. By Mr. Evans it is classed among the non-venereal sores, under the name of “*ulcus erraticum*.” It commences under the form of a pustule, though we rarely possess the opportunity of observing it in this stage, for its actions are too rapid. Those I have possessed have been obtained by the generation of

new sores in patients already under treatment. If we except the phagedænic sore, the treatment of all venereal disease is direct and simple. We can prognosticate with certainty the progress and almost the duration of any form of ulcer, in its primary or secondary form, always excepting sloughing action; while in phagedæna the actions, like the sore, are eccentric, alternately healing and extending, amenable to one form of treatment one day, rejecting it the next; healing in one portion, ulcerating in another; and presenting in the same sore a confined and unnatural combination of granulating, sloughing, and ulcerative actions. During the very early progress of the phagedænic sore there is nothing uniformly characteristic by which to determine it; indeed, it may be doubted whether there is such a disease as the primary phagedænic sore. This doubt has, I conceive, most reasonably been suggested by Mr. Guthrie, in opposition to Sir R. Carmichael, who first systematically described this form of ulcer. Mr. Guthrie considers the phagedænic sore to be dependent on unexplained and probably inexplicable causes, and states that he has frequently seen sores become phagedænic during their progress; and that in fact there is no form of sore warranting Sir R. Carmichael's denomination of a phagedænic primary ulcer.

Sir R. Carmichael has referred certain secondary forms of eruption to this phagedænic sore, considering it a distinct form of disease; at the same time acknowledging that “he had not witnessed it at any earlier period than the second or third week from its commencement,” while Mr. Guthrie is of opinion that any simple form of sore may become phagedænic, and exhibit all the characters of secondary disease, referred by Sir R. Carmichael to the phagedænic ulcer. There is an obvious and important difference in the two views of the subject—primary phagedæna, inferring the presence *ab initio* of a phagedænic poison obtained by contagion, by which it is characterized throughout; while on the other hand, the progress of the sore being subject accidentally only to phagedænic action, would lead necessarily to the opinion, that this action was constitutional, and not dependent on the presence of a specific local poison. For myself, I entertain no doubt whatever, in common with many men of authority, that the phagedænic (absurdly called) venereal disease may arise spontaneously in particular constitutions, holding no relation to specific poison of any kind; and that its peculiar and destructive actions are referable to the constitution that supports them. I fully agree with Mr. Guthrie, that they are not primary, and that any

form of local sore may assume its actions when advanced to a certain stage in those forms of constitution which are the subjects of its ravages. Although often developed by venereal ulcerations, it may as readily be excited by any other, and may extend throughout the whole range of the animal structure, under the aspect of secondary disease, without the previous existence of a primary one. I greatly doubt its being communicable to any constitution save one of its own kind.

There must, indeed, exist some important difference between the actions of a sore extending by phagedæna, and another form of sore extending by common ulceration; and the question here is, whether this peculiar action, denominated phagedænic, is or is not the product of a poison obtained by sexual intercourse. If it be acquired by such intercourse, doubtless the sore ought to exhibit its characters from the commencement; if it be not necessarily so acquired—if any other form of sore destitute of phagedænic action can assume that action at any subsequent stage of its progress—may we not reasonably infer, that such phagedænic action is not the product of a specific poison, but that it is the product of some internal and yet unexplained constitutional cause, independent of, and distinct from, the original poison? Mr. Guthrie asserts that he has seen simple forms of sore become phagedænic. I have seen it often, and indeed I would even hazard a conjecture, that this is the history of a very large proportion of such sores; not that I entertain a doubt but that a certain form of phagedænic sore may exist as such from its commencement, or at least from within a few hours of its first appearance. By phagedænic action is meant that process of extension of a sore, by which its edges appear to melt away; or, as Mr. Wallace expresses it, as though “serrated or nibbled.” The action is chiefly confined to the margin, which the destructive process having undermined, overlaps with an irregular and ragged edge. Of this mode of destruction of soft parts there are various degrees, the most simple of which is characterized by slow action, and is usually covered by a layer of white matter. Here the reparatory action commences on one part of the sore as soon as that of destruction is exhausted, and the two advance together, engaging opposite sides of the sore, each progressing in the same direction; the destructive margin being concave, and the reparative or granulating one convex. From this circumstance it has been named the “horse-shoe sore.” Its action may be compared to that of fire in a field of stubble, extending and destroying in all directions, its activity proportioned

to the favourable or unfavourable nature of the material on which it travels. That the action is purely local may be inferred from the limited extent of its operation, the two actions of health and disease being almost blended. The pain of the sore is not particularly great. In another degree of activity we find more rapid destruction, extending not only along the whole circumference, but throughout the excavated base of the sore. It extends rapidly in all directions, and in the course of two days may equal the size of the half of a large black currant. The base is of a dark red colour. The local pain and constitutional derangement are considerably greater than that attendant on the first form. The third degree is known under the term “sloughing phagedæna,” and is rarely met, except in hospital practice. Its name indicates the extensive and often fatal destruction which marks its progress, and it is well named; for the action is phagedænic, and the product a slough, often of the most formidable dimensions.

Mr. Wallace, who has devoted to phagedænic ulcers a considerable portion of his work on the Venereal Disease, very justly attaches considerable importance to the colour of the slough, as I shall at present term it, which is formed on them. His sub-division of these forms of sore is very extensive, founded not merely on the black or white colour of the slough, but on the irritable and inflamed character of the sore; and the negatives to these give in addition an agreeable variety of phagedænic ulceration, to dilate on which would exceed the limit of an ordinary lecture, and which, with every respect for Mr. Wallace, would, I think, be hardly profitable, inasmuch as nature, in this disease at least, is scarcely consistent with her own indications; and as Mr. Wallace himself says, “there are but few varieties of phagedænic disease which do not run into each other, or exhibit compound characters.”

What is the immediate product of phagedænic action? Mr. Wallace asserts that it is slough, and not pus. He considers those views of ulceration first promulgated by Mr. Hunter, which refer to that process a gradual absorption of the destroyed vital substance, to be erroneous, considering, in the case of venereal ulcer for example, that the constitution must be contaminated by such absorption, did it occur. He refers the ulcerative and sloughing processes to the same actions, varying only in degree; a thin layer of dead matter being separated and broken down in the one case, and a large portion in the other, over which the absorbents exert no influence whatever. He says, “with a magnifying glass of moderate

powers, we may also detect upon an ulcerating surface a stratum of matter more or less solid, and sometimes semi-transparent, formed by the original texture in progress of liquefaction; and that the transitions of the states of ulceration and sloughing are gradual and continuous." According to his views, the whitish matter adhering to the bottom of sores, of which perhaps the best example may be obtained in phagedæna, consists of the debris of former organized matter, which has not been absorbed. He goes further, and asserts that the process of ulceration is merely a modification of that of sloughing, and differing only in degree; for while in the latter change the whole substance is converted into a dark and putrid mass, in the former the animal texture is separated more gradually, and may be seen by a common magnifying glass to be retained on the surface of the ulcer, from which it may be removed by the forceps, "giving some resistance to laceration, and being more or less stringy and tough." I cannot say that the examination I have made with the microscope of these and similar secretions bear out the reasoning of Mr. Wallace; on the contrary, I have always found that the semi-fluid matter which covered these sores is composed of the purulent globules floating in serum. I have examined this matter on frequent occasions, selecting more especially that from sores which bore the nearest resemblance to disorganized matter or slough. I made this inquiry with a full inclination to adopt the doctrine of Mr. W., and with something allied to a hope of its correctness, for I had been disposed to entertain the same views before I read Mr. Wallace's work.

If I had a prejudice, therefore, it was in favour of and not against them; and I confess I was somewhat disappointed in the results I obtained, which I must honestly confess were all opposed to his views, for the fluid is unequivocally pus, and not slough. It differs, however, from common pus in containing less serum, so that a mass of the globules coalesce, forming an apparently condensed substance, which is not very easily penetrated by the glass.

Phagedænic disease, primary or secondary, presents to the finger on pressure no sense of thickening, nor induration. Slight tumefaction is a frequent attendant on the less rapidly ulcerating forms, either with white slough or when destitute of it, but nothing with which to confound the circumscribed thickening of Mr. Hunter's description.

The purely local action of phagedænic disease does not at all weaken the supposition of its constitutional character; the

idea which is conveyed, being that of a structure so organized as to be unable to resist the influence of a poison that would prove inoperative on a structure of a different kind, and in which probably the whole body participates.

Although we are unable to determine by any external indications, with any thing approaching to precision, the characters of those constitutions which are subject to such influence, yet we have no difficulty in determining generally the class of persons who are liable to it; for, negatively, we do not observe it to reign among the vigorous and strong, or the sanguine, nor does it perhaps hold a relation so much to temperament alone, as to temporary health and habits of life. It will attack the weak, whether constitutionally, or whether reduced by disease or treatment. Its ravages are promoted by mercury, when producing frequent pyalism, and perhaps more frequently than from any other cause. It prevails among the dissipated and the dirty, who destroy the natural and wholesome appetite for food by habits of spirit-drinking; and among those forms of constitution which we term the scorbutic, as well as the cachectic.

I have had under my care for three months a gentleman who returned from the West Indies on board a merchantman, where he was attacked by scurvy, from which he alone out of all the ship's company suffered. When I first saw him, my attention was directed to certain purple patches on the back of his hands, caused by the disease from which he had, when I first saw him, recently recovered. He contracted a sore on his arrival at Plymouth, and was salivated; and on reaching London had phimosis, with profuse sanious discharge. I divided his prepuce somewhat unwillingly, and he has been under treatment during three months for many phagedænic sores of the glans and prepuce, of which the wound I made formed the largest.

Although, then, we cannot always determine with certainty, we have often at hand some peculiarities whereon to ground suspicion of the liability of individuals to phagedænic disease. Prejudice and defect of observation class these cases as the invariable product of venereal poison. There is no one fact connected with this subject, which I am more anxious to impress on your minds, than the fallacy of this opinion.

But to return to the primary sore. It may be the immediate product of a pustule or an excoriation. Its early characters may not be distinctly marked. It may possibly be a venerola, or a mere excoriation, which may progress for some days before it exhibits its peculiar characters.

It may then manifest a great propensity to ulcerate irregularly at its margins alone, if of the less active kind, having the "nibbled and serrated" edge of Mr. Wallace; or at the base also if of the more active. The destructive process is carried on less rapidly when the sore is situated on the glans, than when in the fossa, or inner side of the prepuce. The common skin is also less rapidly destroyed, whether of the penis or of the general integuments, unless the sloughing action be superadded; and then there are no bounds to its virulence. On the fossa, or indeed on the glans, it often burrows deeply, laying open the erectile structure of the corpus spongiosum, or extending deeply into the common integuments of the dorsum: its crisis is often obtained by extensive hæmorrhage from the dorsal vessels. The slow form, covered by white matter, is the most frequent; for the extension of which we have no rule to guide us, so fitful, so various, is its action. Stimulants, depletives, escharotics locally applied, general depletion, tonics, mercury, used as constitutional means, may be each and all, at one time or another, both beneficial or injurious. The disease must be seen daily, and prescribed for daily. When in any degree active, the treatment that will prove beneficial on one day, may be worse than useless on the next. The more simple the form, the more difficult its management; or, at least, I have found the more rapidly extending phagedænic disease allied to the sloughing form, and even that disease included, to be more controllable under the treatment first suggested by Mr. Welbank, than the sore covered either with white matter or white slough.

There are three forms of phagedænic primary sore, each of which is a modification of the other, and of which each may exhibit various degrees of activity or irritability.

The first sore (the *venerola superficialis* of Mr. Evans) is not excavated, but formed on a level with the surrounding skin. The nibbled edge may be observed by close examination. It does not extend with the rapidity of either of the other forms, and may remain stationary, or apparently so, for many days or weeks. It is covered by a thin layer of whitish matter, easily removable by the application of a piece of lint, and under which a minute granulating surface appears. It might rather be denominated a simple sore, extending by phagedænic action, than a positively phagedænic sore. Its comparative activity may be estimated by the colour and quantity of the secretion; if progressing favourably, the secretion is small in quantity, and possessing the ordinary qualities of pus. A larger quantity of this matter

on the surface, of more viscid and adherent qualities, indicates an unfavourable condition, and shews a tendency to spread. The quantity and quality of the matter will also correspond with the halo of inflammation around it, which, however, in this sore, is not considerable.

The second form of phagedænic sore which may at any time be assumed by the last described, is characterized by a greater tendency to spread (by erratic action), which extends deeper even when it attacks the glans—is covered by a deeper and denser slough, of a whitish colour, not always readily removed from its surface—has a more inflammatory circumference—is attended by more constitutional derangement, and that generally referable to either mercurial excess, or to the abuse of spirituous drinks. This I have found the least controllable, by simple treatment, of all phagedænic sores. In it we find the constant struggle between the destructive and reparatory actions, and consequently we have here the best example of the horse-shoe sore.

The third form is that which I presume to have been known under the title of the black pox, not in virtue of its colour, which is not black, although it is described as commencing by a black pustule—an appearance which Sir R. Carmichael alone professes to have seen, and that only once in his experienced career. It is characterized by rapidly extending ulceration, both round the circumference and at the base. It most frequently attacks the fossa glandis, and extends along the circle of the fossa in preference to any other direction. It often undermines the penis to a great extent; is attended with great pain, though by no means constantly so; and may occur spontaneously in the worst forms of constitution.

The bubo of phagedænic disease is as irregular and as uncertain as the primary disease. In its form and locality there is nothing remarkable; but its peculiarity exists in its apparent independence of the primary disease. You cannot foretell the future existence of a bubo. It may occur under circumstances of greater or less irritation, and does not advance *pari passu* with the original sore. The swelling may become considerable, stop short of suppuration, and assume the more active form, while the original sore is healing; and *vice versâ*. I have repeatedly seen the bubo of phagedænic sore form in the early stage of the sore, and gradually subside, while the sore was pursuing a career of protracted ulceration. I do not think this form of bubo is liable to suppuration, when compared to the bubo of simple *venerola*, or of gonorrhœa.

The phagedænic ulcer, as may be in-

ferred from the preceding description, produces secondary disease of a very formidable kind. It may appear from six to ten weeks after the disappearance of the primary sore. It presents itself under the form of sore throat and eruption, either of which may precede the other, or both appear together. Whatever form it assume, it is preceded by symptoms of constitutional disturbance, pains in the limbs, headache, accelerated pulse, languor, which are somewhat modified on the development of the eruption. The aspect of the throat is various, but it is generally affected in the first onset on the soft palate and tonsils. These surfaces are inflamed, though not always extensively. A foul ulcer may form on the tonsils, or on any part of the posterior border of the palate. At first there are no peculiar characters with which to determine the nature of the disease. The ulcer spreads with ragged and undermined edges.

The inflammation may extend to the upper surface of the palate, and, gradually advancing, may attack the mucous lining of the nose, from which its extension to the bones is a very general occurrence. Portions of bone come away with hardened crusts formed on the pituitary membrane. The disease attacking the cartilaginous septum may destroy it either partially or entirely. The ossa nasi, or the spongy bones, become involved; first indicated by tenderness on the dorsum, then by inflammation; at length the foundation of the nose appears to crumble down, and the ossa nasi, in a state of necrosis, separate from the frontal bone, leaving the integuments and cartilages of the nostrils the only projection beyond the level of the cheeks.

The back of the pharynx is, however, more frequently the seat of phagedænic disease than any part I have yet alluded to. It appears covered by a layer of white viscid matter, extending beyond the view in all directions. This whitish matter degenerates into brown crusts adhering to the surface, which at times appear almost black and dry.

The eruption appears in the form of pustules, some of which mature, but the majority prematurely burst, and form crusts of various forms and sizes. Some have the hardened base of furuncle, and form tubercles of a red copper colour; some chronic without, but the greater number with, an ulcerated and inflammatory base: these elevated crusts constitute *rupia cachectica*. When the eruption is extensive, it exhibits the compound forms of papulæ or pimples, pustules, tubercles, and of scaly eruption; not, however, the scaly eruption of syphilitic disease, but that of flat shining blotches, not unlike the cicatrices of soft skin. You must also observe that the final stage of all such

eruptions as the above end by desquamation; and this appearance may be, and indeed is, very commonly mistaken for the scaly eruption of syphilis. There are, therefore, two forms of scaly eruption, but neither of them bearing a very close resemblance to the latter rare form of disease. Sometimes the eruptions are of a character to which the term *phlyzaceous* has been applied, which means small tubercles passing into early ulceration, each ulcer, however small, surrounded by an inflammatory ring. It is important to consider the nature of the progress of all these forms of disease, for the purpose of acquiring some insight into the condition of the constitution that generates them. They commence in ulceration, why determined to those particular spots we know not: they exhaust their energies before they are matured. Neither the ulcerative nor the suppurative process appear to appease the activity of the inflammation, which, unlike healthy inflammation, continues unmitigated after the establishment of these ordinary crises. Sometimes the crusts separate, and leave ulcers, which extend rapidly in one part of the body, while they are healing in another, several of such ulcers, like the primary sore, healing on one side and extending on the other; and this is the important diagnosis of phagedænic eruption, which appears like a congregation of local sores, each independent in its action, apparently increasing or granulating, without reference to any general influence derived from the system at large. From the head to the foot the body is sometimes covered with large circular patches of ulceration, varying in size from that of a shilling to that of the palm of the hand, ragged, bleeding at the margin, and covered with whitish matter at the base. The periosteum of the tibia, ulna, or any superficial surface, may become inflamed, but the disease rarely affects the bones primarily. Suppuration and abscess of the periosteum not unfrequently follow. Severe pains in the joints, with swelling from effusion within the cavity, and various other anomalous diseases, occur; but it is not easy to determine how far they, or, indeed, the affection of the bones or periosteum, are the true product of phagedænic disease; or whether these and many other symptoms may not be attributable to the practice, happily in these days somewhat less general, of administering mercury in exterminating doses in every malady which may bear the remotest analogy to venereal disease.

Mercury employed largely and repeatedly in some cachectic habits is competent to the production of all the constitutional forms of disease I have above enumerated—I mean mercury without venereal con-

tamination. Moreover there are certain forms of copper-coloured eruption (by which is meant eruptions of a brownish red, but very unlike the colour of copper), which appear on the face, chest, and arms, forming irregular patches or stains, coupled with small tubercles, and accompanied by pains in the limbs, and the same train of symptoms that attend the approach of the secondary disease of primary phagedæna, and all this may occur in a weakly constitution (and further than that I cannot define it), without either mercurial irritation or primary disease of any description, that can warrant a suspicion of venereal origin.

Of this fact I am confident:—that it more frequently follows primary disease. I do not doubt, but I am most desirous of impressing on your minds the fact, that the above train of symptoms will occasionally follow not only cachexia with mercury, but cachexia without mercury.

It is constantly urged by the advocates of mercury, that similar diseases to the above do not follow the large administration of that mineral, when employed for the cure of other diseases; and I grant that they do not frequently follow it; but I assert most positively that *they occasionally do follow it*; and were it administered under the same form and circumstances, they would succeed to it much more frequently. By the physician mercury is employed in the treatment of internal inflammation. It is employed in that and various other forms of disease in India, where it is administered in enormous doses. In the first place, although mercurial action is often by the physician pushed to ptyalism, yet its effects, though severe, are not so protracted; and they are not commonly repeated to the extent of two, three, or four distinct salivations, as we have frequent opportunities of witnessing, when employed with the intent of eradicating venereal poison. Again, these other diseases being mostly of an inflammatory type, indicate a force and vigour of constitution unfavourable to the development of phagedænic disease. We do not meet with inflammatory diseases in cachectic constitutions, neither can we look for a phagedænic diathesis, if I may use the term, in those subject to inflammation. Besides, the supposition does not appear to me very unreasonable, that the presence of any important disease, whether inflammatory or malignant, may afford to the constitution some protection against consequences that might occur without it, or that the two forms of disease may be incompatible, supposing the mercury to have a serious enemy to contend with. But phagedænic disease *does* occur after mercury administered for non-venereal disease, in cases in which that disease has never existed, but in the form of a short-lived gonorrhœa,

and also in cases in which venereal disease has never existed at all.

Some three years ago, I attended the case of a woman of 53 years of age, who, in consequence of ill health, was sent home from India, where she had been severely mercurialized for supposed liver disease. Soon after her arrival in England, without the presence of intervening disease, she became the subject of phagedænic ulceration, which appeared on various parts of her body, and of ulceration of the pharynx. She gave a strenuous and indignant denial to the somewhat superfluous inquiry relative to the possible venereal origin of her malady. She was again salivated, and died.

I have known phagedænic inflammation of the pituitary membrane, necrosis of the spongy bones, and complete destruction of the septum narium, occur in two persons who, having never been the subjects of venereal affection of any description, had been severely and long continuously salivated for paralysis of the limbs. But it is needless to multiply cases which in reality add no force to the statement, but perhaps rather weaken it; and I shall therefore content myself by repeating my assurance—1st, that phagedænic is by no means necessarily venereal disease; 2d, that phagedæna may occur in certain constitutions independently of venereal disease, as the product of long-continued mercurial action; and 3d, that phagedæna may occur in cachectic habits, independently of either mercurial or venereal influence.

OBSERVATIONS

ON

COMPLICATED SURGICAL INJURIES,

INCLUDING GUN-SHOT AND OTHER WOUNDS.

By RUTHERFORD ALCOCK, K.T.S. &c.

Late Deputy Inspector-General of Hospitals with the Auxiliary Forces in Portugal and Spain.

(As delivered in his Lectures at Sydenham College School of Medicine.)

[Continued from p. 242.]

IV.—ON INJURIES OF THE EXTREMITIES COMPLICATED BY LESION OF BLOOD-VESSELS AND NERVES.

Rule of practice in recent cases.—Difficulties in secondary hæmorrhage with fracture of femur.—Amputation advisable.—Case.—Secondary hæmorrhage of the leg, with fracture.—Cases.—Exception to general rule.—Not applicable to upper extremity.—Mode of arresting hæmorrhage in the hand.—Injuries of the foot.—Injury to both artery and vein.—Amputation unavoidable.—Lesion of nerves.

In the last lecture, the nature, and principles of treatment, of some of the com-

plications connected with gun-shot fractures in the extremities were described. The complication I have reserved for the last is, however, the most troublesome and destructive, sometimes to limb, and not seldom to life. I allude to lesion of blood-vessels and nerves.

I have already stated the result of my own experience as to the frequency of these cases; and although I conclude that there is a larger average than the number stated by Mr. Guthrie, yet still they are fortunately not frequent—considerably less than one per cent. I say fortunately, for loss of a limb or of life is the consequence in a great majority of cases.

The practice is clear enough in a recent case; and to cut down upon the bleeding artery wherever it may be wounded can offer comparatively few difficulties to a surgeon well acquainted with the anatomy of the parts. It is far otherwise when hæmorrhage occurs by the detaching of the sloughs on the tenth, twelfth, or fourteenth day. Time enough has then elapsed for the superposition of extensive disease in the limb—for swelling, inflammation, supuration, infiltration of muscles and cellular tissue with pus—the whole worse confounded with coagulated and fluid blood. These together so essentially alter tissues and the relative position of parts, that the ablest surgeons are likely to be foiled in the endeavour to take up deep-seated vessels in the midst of this putrid mass of disease. I have several times had to operate in such cases, and they have always proved the most difficult and anxious of any operations it has fallen to my lot to perform, and too often unsatisfactory in their result.

Of all the injuries to which the surgeon is called to lend the aid of science, perhaps there are none more harassing to him, or more dangerous and painful to the patient, than fractures complicated with wounded arteries, when the hæmorrhage occurs during the suppurative stage. It is in vain that anatomists describe to a hair's breadth the course of an artery: at this period it is not enough to know the relative anatomy of the parts injured—to be able to distinguish with facility in the healthy body, artery, vein, and nerve from each other by their texture—a surgeon thus prepared, bold, dexterous, and cool, will still occasionally fail.

The cutting down upon the arteries in the healthy living body to a well-informed surgeon is a certain operation, in which failure cannot be the result; at every step of the operation there is a land-mark; he places the patient or his limbs in whatever position he likes; he travels, in fact, on a well-beaten track, and cannot fail without gross ignorance and inefficiency. The case, as I have said, is very much altered when there is a shattered bone—a limb swelled by inflammation, and gorged with coagulated blood—neither time nor opportunity for removing the patient, and very little scope allowed even for change of position in the limb or body. The surgeon now takes the scalpel in his hand under circumstances of the most trying nature. Where are his land-marks? He divides the integuments in the direction of the artery he supposes to be the one injured; but then what follows? He comes upon cellular tissue in a state of ulceration—injected with blood, thickened and infiltrated with lymph: he cuts deeper—looks for his guiding tendon or the edge of a muscle—tendon, clotted blood, slough, artery, and vein, all are involved in one diseased structure! Well, the artery is compressed—the hæmorrhage is restrained—coagula, fragments of bone, and detached sloughs, are cleared out—and now he must be upon the artery—where is it? He looks in the line where he deems it ought to be, and sees nothing he can distinguish from the surrounding ragged and diseased structures—the pressure is relaxed—the whole of the bottom of the wound is instantly covered with blood—this is sponged away—again and again he sees the florid arterial blood spring forth from the bottom of the wound, but not from a bleeding mouth—not from a point, but at the same instant apparently from the whole of the ragged structure at the bottom of the wound; and, at last, it will occasionally happen that, convinced here his accurate anatomical knowledge is at fault, his manual dexterity unavailing, he will feel compelled to adopt some other measure. This is, in truth, a case where the best anatomist and most skilful operator may be disappointed and baffled.

I do not draw this description from fancy—above all, I do not give it that you may infer anatomical knowledge in such cases of little value. On the con-

trary, if the best acquirements cannot always ensure success, to attempt to operate in such instance without them would be the act of a madman, reckless alike of his patient's life and his own reputation.

Much judgment and experience are required to enable the surgeon to decide rightly on the practice which should be adopted in cases of gun-shot fracture with lesion of artery. If, in a recent wound, he will secure the artery, and other circumstances being favourable, the limb may be saved. If in a fractured femur, however, the femoral artery give way, particularly during treatment, when the thigh is necessarily much diseased, amputation will, I believe, always be found the best step. Nor is the diseased state of the soft parts, even where the incision must be made, sufficient to make the operation inexpedient: several remarkable cases illustrating this I could relate to you, and also of the absence of all necessity for dissecting out the sides of diseased sinuses. The following abstract will serve as a type for the class of cases to which I allude, and bears upon both the points under consideration. Here is the preparation resulting from the case.

Series of 5th May.—Charles Owens, æt. 25, 1st regiment, admitted with a slightly comminuted gun-shot fracture of the femur, oblique, extending through the whole of the middle third. Inflammation rapidly supervened, seeming to implicate the knee, with considerable heat and tumefaction of the whole limb. Suppuration commenced with an abundant discharge on the 13th day. Diarrhœa had supervened two days previously, and continued, with slight intermission, up to the 50th day. Loss of appetite—night sweats—loss of sleep—marked the progress of the case. On the 25th day a large abscess had formed in the lower and inner part of the thigh, causing him great pain, which was relieved by a counter-opening, whence flowed an abundant discharge of matter. From the 30th day the discharge considerably decreased. On the 50th day I was called suddenly to him while engaged in the morning visit, and found blood *per saltum* pouring from the internal wound. No moderate pressure on the artery, as it crosses over the spine of the ilium, was sufficient to arrest it, and on a momentary closing of one wound the

blood burst out at the opposite orifice. Pressure with a firm pad over the handle of the tourniquet succeeded in restraining the hæmorrhage.

There was every reason to believe that the femoral artery had sloughed, or was injured by a fragment of bone, and taking into account the extensive disease of all the surrounding parts, I deemed it more expedient at once to remove the limb above the fracture, than to attempt to secure the artery.

This case, together with twelve other cases of gun-shot fracture of the femur, I had confided to Staff-Surgeon Johnston, of whose unremitting attention and excellent knowledge of every part of his profession I had received abundant proof. Indeed, to that gentleman am I much indebted for this rare and certainly valuable collection of preparations, so amply illustrating the subject of gun-shot wounds; for he zealously devoted much labour to carry into effect my wishes respecting them at all times and for a very long period.

To Mr. Johnston I left the operation, which was performed in a way well becoming an old pupil of Mr. Liston's. The parts where it was necessary to perform the operation were in a very unfavourable state. The muscles were greatly infiltrated and pale, the parts divided hæmorrhagic, and the vessels deprived of all power of retraction. An abscess ran up on the outside to a considerable extent, which I recommended should be left without any attempt to remove the sides. The vein was secured with a fine ligature, to stop a troublesome bleeding. The ligatures were cut short. As a zealous admirer of Mr. Liston's modes of operation, Mr. Johnston adopted the flap operation. The patient sank to an alarming degree during and for some time after the amputation.

The cure went on favourably, and the stump was entirely healed on the 70th day after the operation, notwithstanding the diarrhœa had continued for a considerable time subsequent. On examining the limb, the point of the superior shaft was found pressing against the artery: it had produced a slough, and ultimately rupture of the coats, the slough extending for about half an inch (see figs. 1, 2, 3). A large sac filled with coagula was cleared out, originally formed probably by matter. The feeling of power which

he used to express of moving the limb seemed to have arisen from the firm overlapping of the very obliquely fractured shafts. On dissecting the limb, a second ball (for both the entrance and exit of one existed from the first moment) fell out, which had been partly flattened by impinging against the bone.

The situation which it occupied was not observed; the entrance of a second ball not having been suspected.

Dissection shewed that this, which promised, notwithstanding the diarrhœa and profuse discharge, better than the parallel cases, from the straightness of the limb, absence of pain, and slight

comminution, was, in effect, before the hæmorrhage, quite hopeless. As you see in the preparation (figs. 1, 2), nature has made but very insufficient efforts to unite the bones, the callus thrown out is trifling, in comparison to the injury. In spite of an alarming exhaustion from hæmorrhage, and the shock of the operation—notwithstanding an obstinate diarrhœa and worms, he steadily improved from the first day after the operation, and was invalided with a good, sound, and fleshy stump.

Amputation in these cases is somewhat like Alexander's method of untying the Gordian knot. It cannot, or rather it ought not, to be resorted to except as a last resource. It must be held better by the surgeon, and so it will by the majority of patients, to lose a limb than life; but it must never be forgotten how fearful is the loss even of a leg or an arm, and consequently every means at our command should be employed to avert so painful an alternative.

It is no uncommon case among those which occur of secondary hæmorrhage, to find bleeding from the anterior or posterior arteries of the leg complicating a fracture of one or both bones. Here the arteries are not of very large

calibre; they lie, for the greater part of their course, deeply buried in the muscular parts, considerably increasing the difficulty of placing a ligature upon them; yet, to amputate a leg which might otherwise be saved, because one of these arteries may be wounded and bleeds, cannot be contemplated under any ordinary circumstances.

When the parts are much swelled, however, diseased and engorged with blood, it will occasionally happen that an attempt to get at the bleeding point and secure it, seems altogether hopeless. I have already sufficiently dwelt upon the proper line of practice as a general rule—viz. to cut down through the intervening parts, and put a ligature on the artery at the injured part, above and below. The following is a case which must be taken as an exception, where that practice could not be adopted:—

Some three weeks after the action of the 5th of May, 1836, I was suddenly sent for by the orderly medical officer of the day of one of the hospitals. A violent hæmorrhage had occurred in a wounded officer, who, up to that period, by a very unusual chance, had escaped my notice. I found him blanched with pain, anxious suffering, and some little loss of blood: the orderly officer, one of the assistant surgeons, in no small perturbation, almost as white as his patient, watching the leg and squeezing the artery in the groin.

On examining the leg, I found a musket-ball had entered immediately below the head of the fibula of the left leg, and, traversing obliquely, made its exit low down on the inner side. I found repeated, but not long-continued, hæmorrhage had taken place from the upper and external wound. The leg was swelled, tense, and gorged with blood; extensive suppuration had diseased the whole limb. To cut down here for the anterior tibial, the artery most likely wounded, as it passes through the interosseous membrane to the anterior tibial region, in such a diseased state of the limb, seemed to offer so little hope of successful issue that I felt unwilling to add to his sufferings, which he expressed to be very great, by trying. To remove the limb was an extreme measure, to which I was still more averse. I therefore tied the femoral artery, which was very speedily and easily accomplished, and I was the

more inclined to adopt this practice from having already seen two cases in which it had been completely successful.

For several days he was free from pain, the swelling and tension of the leg disappeared, and I began to entertain sanguine hopes of a successful issue; but on the fifth evening I was again suddenly summoned to his bed-side; a still more violent hæmorrhage had taken place, not from the leg, but where the femoral had been tied, for which I was totally unprepared: the ease and gentleness with which the ligature had been placed upon the artery seeming to preclude the possibility of any accident there. On cutting down and separating a few partial adhesions, the artery was found to have sloughed; a gaping and ragged opening presenting in the artery. The vessel was secured again, half an inch higher up, but this time with greater difficulty; all the surrounding parts being more or less diseased, the vein closely adhering.

The patient resignation with which he bore his sufferings, and yet his anxiety to recover, independent of the peculiar circumstances of his case, interested me even more deeply than usual in the issue. After the second operation, while anxiously inquiring what hopes I entertained of his recovery, and expressing a grateful confidence in my exertions to effect it, I certainly felt as though I could have given a year of my own life for the power of adding it to his. I could not speak very confidently to him, and his thoughts wandering to the action which had cost him so dearly, still viewing it with a soldier's feelings, he gave expression to a bitter and repining thought, that no mark of honour even told those who were absent how he had done his duty in the field. I forget now by what mistake or chance he had not been included among those decorated for that action (for it appeared he had been noticed), but on returning in the evening later to see him, I placed in his hand a letter from the military secretary, by the Lieutenant-General's command, conferring a decoration and promotion at the same time, for his gallant conduct on the 5th of May. I almost rued my wish to give him at least one unalloyed pleasure in his trials; the gratification of two wishes dear to him even while life was doubtful, af-

fected him so deeply. As he grasped my hand, the tears chased each other down his cheeks, and I began to think myself but a very indifferent doctor for my pains. Poor fellow! he died about a week subsequent to this, after labouring many days under a high irritative or sympathetic fever. The column of blood beat so strongly against the ligature, and the palpitation of the heart was so irregular and forcible, that I had daily feared to hear of his death by another hæmorrhage. The second operation however, was completely successful, both as related to the artery of the leg and the seat of ligature. On making the post-mortem, I found a pretty strong and adherent fibrinous plug in the upper portion of the artery. The vein and the lower part of the artery, although surrounded by disease, were thickened, and sufficiently consolidated to give fair promise of ultimate cure, as regarded the operation.

On making an incision through the external shot-hole down to the anterior tibial artery, a small portion of ball was found lodged, lying over the artery, exactly where it passes from the back to the front of the leg, which it had considerably lacerated. The ball had also passed obliquely through the head of the tibia, crumbling the bone very much in its passage; without, however, directly, by any fissure, implicating the joint. The posterior tibial and peroneal were safe; the soft parts were very extensively diseased.

The operation of tying the humeral artery for wounds of the radial and ulnar, is less admissible, inasmuch as it very rarely succeeds: the anastomosis is so free by the recurrent arteries, that I have seen the circulation re-established, and the hæmorrhage recur in three days, in a case where this expedient was adopted.

When hæmorrhage occurs in gunshot fractures of the hand, among the branches of the palmar arches, there is but little hope of applying a ligature successfully to the bleeding point or points. Well-adapted pressure and cold, however, will generally succeed. A good example of this occurred in one of the hospitals at Oporto, and highly creditable to the gentleman (Mr. Blair, now of Colchester) under whose care the patient had been placed. In a complicated wound of the hand, with fracture of the metacarpal bones, secondary

hæmorrhage supervened, without the possibility of discovering the mouths of the vessels from whence the bleeding came. By well-adapted and graduated compresses at the wrist (the one next the skin of cork), bearing upon the radial and ulnar arteries—by pressure, and the application of a refrigerant lotion in the palm—the hæmorrhage was successfully and permanently restrained, and a useful hand was saved.

These hæmorrhages occur less frequently in the foot; and it is remarkable the degree of injury the tarsal and metatarsal bones will sustain without entailing the loss of any portion of the limb. I have had many cases under my observation, where balls have traversed obliquely the bones of the tarsus, or both tarsus and metatarsus, and yet the foot, after a more or less tedious exfoliation, has been saved, and the wounds healed. Unless, therefore, the ankle-joint be seriously implicated, do not hastily condemn the limb. Nature will do much, if the surgeon aiding only, will not unnecessarily interfere.

To conclude the subject of hæmorrhage from wounded arteries in the extremities, I may observe, that if both the principal artery and vein of a limb be divided, amputation is the only resource, for mortification will otherwise inevitably take place.

A case of this kind occurred in September 1832, at Oporto, where the vitality of both humeral artery and veins was destroyed by the passage of a ball. He was in the same Portuguese hospital as the fractured forearm, and he was pointed out as a case where the Portuguese medical officers had decided in a contrary sense—viz. that no operation could with propriety be performed, because mortification had already extended to the chest. On examining the patient, I found the hand mortified, the same action extending nearly to the wound made by the exit of the ball. The side of the thorax adjoining was also livid and bluish, but it required but a glance to see that this was caused by the blow received from the ball at its exit, and had nothing to do with the mortification of the arm. I amputated the limb, therefore, amidst many grave doubts, in the presence of half the medical men attached to the Portuguese army, removing the arm at the shoulder, but leaving the head of the humerus in the joint; and suffi-

ciently demonstrated to them that where my knife had passed no mortification had extended.

At the first dressing, the stump had healed nearly its whole extent by the first incision; but it was sultry weather, the arrangements of the hospital were bad, and I had the vexation of seeing my patient, after so auspicious a commencement, carried off by fever.

A lesion of the principal nerve is very uncommon, it is fatal to the usefulness of the limb. I have seen a case of lesion of the anterior tibial nerve, in a gun-shot wound of the leg, productive of a train of very distressing symptoms: the upper extremity became bulbous, and the slightest contact, from dressing, or the shaking of the room by a heavy step even, made him shriek with anguish; it was exposed, and about half an inch cut off, with complete relief to these symptoms. Here you see the bulb-like extremity, which was removed.

DESCRIPTION

OF AN

IMMOVEABLE APPARATUS,

FOR THE MORE EFFICIENT TREATMENT OF
COMPOUND FRACTURES OF THE LEG, OF
SIMPLE FRACTURES WITHOUT SPLINTS,
AND OF INJURIES TO THE ANKLE JOINT.

To the Editor of the Medical Gazette.

SIR,

If you deem the accompanying description of an apparatus which I have for some years past been in the habit of using in the treatment of severe compound fractures of the leg worthy of a place in your valuable journal, I shall feel obliged by its insertion.

I remain respectfully yours,

F. A. BULLEY,

Surgeon to the Royal Berkshire Hospital,
Reading; and to Reading Dispensary.

I am aware that I may be thought guilty of presumption, and a desire to arrogate to myself the merit of discovery, in venturing to suggest any improvement in the ordinary method of treating severe compound fractures of the leg; but as the results of injuries of this description are frequently so uncertain, and as frequently involve the credit of the surgeon, and the loss of life or

limb of the unfortunate sufferers, I am sure that any hint, however slight, will be received in the spirit in which it is intended. I therefore take the liberty of offering a few observations on the means I have for some years past been in the habit of using to alleviate the protracted suffering incident to cases of this kind, with the view of bringing their management more immediately under the influence of mechanical art.

The frequency of accidents of this nature (some of them of extraordinary severity) which, owing to the vicinity of the works of the Great Western Railway, have occurred in the neighbourhood of this town, has given me extended opportunities of closely observing their progress, and remarking the comparative inapplicability of the mechanical means employed to assist in the restoration of the injured parts, more especially as regards their complexity and expensive construction, and their utter incapacity to produce what I insist upon being absolutely indispensable, *i. e.* a permanently elevated position of the fractured limb above the horizontal level of the body, and this led me to direct my attention particularly to this part of the treatment. The result has been that, after many trials, I succeeded in constructing the apparatus which I am now anxious to describe, and which has since been used in the casualty ward of the Dispensary and in private practice, both by myself and my eminent colleague, Mr. Maurice, with the most happy and successful results.

It has been acknowledged by surgical authorities of all countries, from the days of Heister down to the present time, that the invention of any apparatus for the treatment of compound fractures of the leg, which would have the effect of bringing the injured limb into an easy elevated position above the level of the body, and so retaining it, was a great desideratum. The subject has therefore at various times engaged the attention of mechanical surgeons, and many ingenious but elaborate and expensive contrivances have resulted. They have generally however been found to fall short of the object intended. The apparatus invented by Mr. Hagedorn for the suspension of the limb, approaches more nearly to the attainment of the required position, than any I can call to mind; but it is probable it can never be brought into general use

owing to the intricacy of its machinery, which is difficult to understand, its liability to derangement, and the impossibility of adopting it in hospitals, or the houses of the poor, who are most frequently the subjects of these accidents.

There can be no doubt, then, that the end to be principally aimed at in the treatment of compound fractures of the leg is to obtain the elevation of the injured limb considerably above the level of the body, in order to prevent excessive vascular engorgement, and to moderate, in some degree, the inflammation and subsequent suppurative process which almost always follows in the train of these accidents. The apparatus I am about to describe accomplishes this purpose certainly and easily, and has the additional advantage of remaining immoveably fixed, during the whole progress of the cure, in the position which it assumes when first applied; my object being to suggest a simple and economical contrivance, by which all the advantages to be derived from the permanently elevated position, may be insured at little cost and of easy application.

I have found that the apparatus I am about to describe has the effect of bringing the muscles of the fractured limb into a state of the most complete repose, such as is not to be obtained by any of the machines in ordinary use; and in proof of this I can safely say, that I have never known, in any case where it has been employed, the occurrence at any period of the treatment of any painful spasm, or muscular catchings, or any consequent displacement of the fractured ends of the bone.

The apparatus itself is simple in the extreme. Its three sides are formed of beech boards, an inch thick, which give it great solidity, and, from its peculiar construction, a state of permanent immobility. It has no machinery to regulate the inclination of the planes, as its mode of action depends upon a fixed mechanical principle; it cannot, therefore, be made to answer the purpose of a double-inclined plane, its only object being to produce the elevation of the fractured limb in a permanent and easy position above the level of the body. *A* is the cross bar upon which the machine moves. The pressure of the nates and lower part of the trunk upon the thigh-piece at *C* depresses it, and consequently raises that portion of the

machine upon which the leg of the patient rests, by its partial revolution upon the cross bar *A*. By this pressure, that portion of the machine anterior to the transverse bar (*i. e.* from *A* to *C* constituting its long lever) becomes imbedded in the mattress, and secures the permanently immoveable position of the apparatus. It may be said that on the removal of the nates and trunk from the thigh-piece at *C*, the machine would resume the position of the double-inclined plane, as it appears in the cut; but this will be found not to occur, as it is prevented by the greater length and weight of the lever from *A* to *C*. There is a double row of pegs upon the upper plane, which are moveable, and afford great facility in dressing the limb: between them is placed a long pad covered with oiled silk, the edges of which are bent up between the pegs, so as to form a hollow bed for the leg.

The footboard *B* is so constructed as to slide in a groove in the upper plane, for the purpose of regulating its required length. In the last improvement, it is rather a greater inclination than is represented in the drawing, in order to produce more perfect flexion of the foot. Into its upper part is inserted a curved iron rod, which extends horizontally over the lower part of the machine. This rod is formed at its extremity into loops, over which are drawn the tapes of a sling, which are placed under the leg just posterior to the os calcis. I have found this sling to be useful in regulating the lower portion of the fractured bone, more steadily and tenderly than it could be done by hand, by slightly tightening the tapes when necessary; and also in relieving the exquisite neuralgia, which so often affects the heel in long standing cases, and the sloughing of the integuments from pressure. A very slight movement of the tapes will effect this without the least displacement of the

fractured ends of the bone. I may here mention, that in the accompanying woodcut the angle of incidence of the planes is made to appear too great, owing to a mistake of the artist. An apparatus made *exactly* according to the drawing would not produce any material elevation of the limb, but it serves very well to explain the action of the machine.

Mr. Weiss, of the Strand, at whose house the apparatus may be seen, has undertaken to construct it, after a pattern I sent him, and to explain its use according to the directions which accompanied it. A model of the machine may also be seen in the Museum of the Society of Arts, where it has been deposited at the request of a gentleman connected with that institution.

I conclude with some general directions for its application:—A piece of deal board, about 8 inches wide, must be placed across the bedstead, on whose frame it would rest at the distance of about 18 inches from the foot; over this are to be placed the mattress, bed, and sheets. The cross bar of the machine is then to be placed in a line parallel to and over this board, of course the mattress, &c. intervening. On placing the limb upon the machine it will be seen that the weight of the body depresses the long lever at *C*, and therefore raises the lower part of the apparatus, in consequence of the board across the bars of the bed preventing the depression of the machine at *A*. Its action may be said altogether to depend upon the movement of the long lever anterior to the cross bar upon the bar itself.

I will not occupy your valuable pages at greater length, trusting you will allow me in a future number to make some further observations on the cases of compound fracture, in which I have used my invention with success; as well as some remarks upon its ap-

plication to the treatment of simple fractures without splints, and of some other injuries affecting the lower extremity.

ON THE ADVANTAGES OF A
SPECULUM CUSHION.

By J. L. FENNER, ESQ. M.R.C.S.

(For the Medical Gazette.)

ONE of the most important modern improvements in the art of healing, in this country, is the departure from the conjectural mode of treating obstinate diseases of the uterus, and the adoption of physical examination by the speculum, so as to bring the various changes which occur in that organ within the scope of ocular examination, and enable them to be studied with as much accuracy as the ophthalmic surgeon displays in the investigation of his peculiar cases. The advantages of the speculum uteri arise from the same indisputable principle which has ever been acted on in the practice of ophthalmic and general surgery. By its employment cases which had been previously mistaken or overlooked—sufficient in number and importance to silence the abettors of the conjectured system of treatment—are daily becoming revealed in their true character.

On the introduction of a comparatively new instrument into the *private practice* of medical men, it might have been naturally expected that there would be a variety of opinions relative to the form of the instrument, and that each practitioner would extol that with which he was most conversant, without considering the respective merits of each, or what desideratum still remained to be accomplished by the inventive faculty in either one or the other of them. Hence Ricord's two-bladed speculum is the *only one* adopted by some; but this instrument is made but of *one size* for *every case*, and, moreover, affords not the least protection to the surrounding parts when caustic applications or leeches are used. The three and four-bladed specula are severally extolled, and are liable to the same objections. The metallic tube of Recamier, and its imitations in glass, find their advocates also; these possess the anatomical absurdity of gradually increasing in cir-

cumference towards the handle to at least twice the size of the end in contact with the os uteri. Thus only an imperfect view is afforded of a very small portion of the cervix uteri, while the large diameter of the speculum is preposterously applied to the perineal portion of the vagina, the part the least disposed to dilate, and the most sensitive of pressure.

A tube of glass, or German silver, two lines in thickness, if made of the *same diameter throughout*, possesses every advantage of the various bladed specula; and if the difficulty of passing, without giving pain, a tube of sufficiently large size to expose the whole extent of the cervix uteri be obviated, it must be superior to any other form of speculum, being free from the objections already stated. Without the addition of artificial contrivance, the introduction of such a tube of sufficiently large diameter would be attended, in many cases, with pain,—probably with injury. For the purpose of using a tube of requisite size with facility, and without pain, I attach an air-cushion in such manner that its soft elastic projection might previously produce dilatation, and, by overlapping, might protect the parts from the pressure of the edges of the tube, as seen in the accompanying sketch.

Small bladders, or the crops of poultry, partially distended with air, and disguised, by being stained with orchel, answer the purpose of the cushions, and can readily be procured. The cushion is formed by twisting the depending portion of the bladder so as to force the air into its superior part, and then tying it with a silken cord in a slip-knot, leaving the end long enough to extend below the bottom of the tube, (*fig. 2*). As represented in the sketch ready for introduction, it is to be smeared with some unctuous substance, and then, being held in the right hand, the cushion is to be applied to the vulva with firm but gentle pressure, and very gradually passed on in the direction in which the cervix uteri has been previously discovered, by the taxis, to be situated. As soon as the speculum, with its cushion, has passed the perineal portion of the vagina and has entered the pelvic cavity, the cord (*fig. 2*) is drawn to untie the slip-knot, and enable the air which distended the upper portion, and formed the cushion, to rush into the depending part; when, by

means of the cord (*fig. 1*) the tube is left clear, by the bladder being withdrawn.

The speculum cushion was invented for the especial relief of cases of irritation and inflammation, which thus may be examined without producing pain, and a consequent increase of symptoms. In cases where little irritability exists, I adopt a more simple plan, but upon the same principle of producing previous dilatation before the edges of the tube press on the vaginal structure. A piece of box-wood of two inches in length is, by a turner, accurately fitted to the inner edge of the tube, one half-inch of the end being conically sloped to a rounded extremity. By boring a hole in each cylinder, a common handle may be used for various sizes, and may be removed when not in use. I trust that

this will be rendered sufficiently intelligible by looking at the former sketch. The part overlapping the edges of the tube is supposed to be removed, and the cushion to assume a more conical form. Where the slip-knot appears may be supposed to be the part of the cylinder where the hole is made to receive the common handle; and, parallel to this, if the stem (*fig. 3*) be the handle, the cylinder may be removed as soon as the tube has passed the perineal portion of the vagina.

My speculum case contains tubes of three sizes two lines in thickness, and five inches in length. The diameter of the smallest size which I employ is one inch, including the thickness of the tube; the second is one inch and a quarter; the third measures one inch and a half in diameter. Besides the advantages of introducing by this mode the tubular speculum, with facility and without pain, and gaining by it every possible information, it possesses peculiar intrinsic merits such as the following:—The whole extent of the mucons coat of the vagina can be explored most accurately, and passed in review under the eye as it is pressed into the cavity of the tube. I lately attended a case of leucorrhœa with one of the most able advocates of Ricord, and discovered, by means of the tube, three chaps on the posterior part of the vagina, which could never have been seen with a bladed speculum. The minor operations so frequently required in the treatment of diseases of the uterus, are also rendered more efficacious and safe by the use of the tube, which may remain a sufficient time without causing any pain. The application of nitrate of silver, ten grains, in a drachm of water—most useful in abrasion or ulceration of the os and cervix uteri—may be readily used. The injecting of the cavity of the uterus with the same solution, when the peculiar glairy discharge is seen to issue from the organ, may be readily accomplished, not by the instruments usually sold for the purpose, but by a silver canula fitted to a small bone syringe: the unimpregnated uterus will contain but about half a drachm of fluid. Leeches to the os and cervix uteri, so valuable in congestive and inflammatory engorgement, and at the critical periods of amenorrhœa and dysmenorrhœa, may, by the tube, be advantageously applied to a large circumference; but where the os

uteri is seen to be open, I would suggest the application of a piece of lint to prevent the ingress of the leeches, as troublesome though not dangerous symptoms would presently supervene.

In the above engraving I have given a sketch of a small mop or brush (*fig. 3.*) one of the most useful and convenient, though the most simple instrument for removing mucus and other substances from the os and cervix uteri, and enabling its structure to be clearly examined, and also for applying solution of caustic, &c. It is a skewer of wood, about six inches in length, having a piece of lint or wadding tied round the top.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abrégé.”—D'ALEMBERT.

The Principles and Practice of Medicine, founded on the most extensive experience in Public Hospitals and Private Practice, and developed in a Course of Lectures delivered at University College, London. By JOHN ELLIOTSON, M.D. F.R.S. Edited by Dr. Rogers. pp. 1080.

How much soever of disrepute may have attached to Dr. Elliotson on account of his recent mesmeric hallucination, few we think will be disposed to question his zeal and activity as a physician and as a teacher of the Principles and Practice of Medicine. We are glad to perceive in the work before us no mention of mesmerism nor of the magnetic Miss O'Key, whose performances we opine have attracted quite as much of public attention as any *prima donna* could expect or desire. It would have been a subject for deep regret that the details of such a juggle as animal magnetism should go down the stream of time in the same bark, with the judicious views, philosophical deductions, and sound methods of treatment, here developed.

Dr. Elliotson ought to feel highly grateful to the institutors of hebdomadal medical journals: had there been no MEDICAL GAZETTE or LANCET he might have fared in 1838 as in 1818. He gives the following account of his professional experience:—

“For many years I toiled, and saw

most of my contemporaries, nay of my juniors (who worked less, but were wiser in their generation) pass by me. I published work after work—edition after edition; and paper after paper; was honoured with a place in the Transactions of the first medical society in Europe. I was physician to a large metropolitan hospital; and had attended there, and gratuitously out of doors, above twenty thousand patients. But in vain. In 1828 my profession was no more lucrative to me, was as short of my actual expenses as it had been in 1818. At that time the LANCET was pleased now and then to publish a clinical lecture delivered by me at St. Thomas's Hospital; and my practice at once doubled. The following year it published the greater part as I delivered them, and my practice doubled again. Last season the LANCET published them all, the MEDICAL GAZETTE followed its example, and my practice has now doubled a third time.”—P. 10.

It will be generally admitted that to an extensive acquaintance with physiology and pathology, Dr. Elliotson unites the faculty of accurate diagnosis and acute discrimination of the best methods of treating disease.

The point on which we chiefly differ from Dr. E., relates to the doses of the remedies, which we think he sometimes carries to an injudicious, not to say dangerous extent. In reference to this part of the subject we subjoin the following extract:—

“Much remains to be accomplished in the discovery both of the virtues of medicines already in use, and of new medicines, or such modifications of old ones, as almost entitle them to the epithet ‘new.’ Every advance in our knowledge of the essential nature of diseases, will no doubt enable us to improve our application of remedies upon general principles;—to improve our ‘general indications.’ But without any additional knowledge of the nature of diseases, cautious trials—guided by the best analogy we may discern, or by some fortuitous occurrence—will enable us (if we are disposed to labour) to effect much in extending our knowledge of the powers of particular remedies over particular diseases. Lord Bacon regrets that physicians apply themselves so exclusively to general indications;—neglecting the peculiar properties of remedies in particular dis-

eases. Such experimental facts, however insulated they may at first appear, gradually arrange themselves, with others, into general principles; and thus what is at first little better than empiricism becomes science. I confess that I look with more hope to this source of improvement, than to any other."

—*Preliminary Observations*, p. xx.

The learned professor advises students "not to plague themselves about nosological arrangements." He thinks, however, Cullen's First Lines, by Gregory, the best they can peruse. He adds, "there are many other excellent works;—Dr. G. Gregory's, Dr. Mackintosh's, Dr. Good's, &c. His own method embraces a two-fold arrangement."

"First, I shall consider general diseases, such as affect every or most parts of the body—inflammation, scrofula, and various other organic diseases; and afterwards, having considered all the affections which may attack any part of the body, I shall proceed to consider those affections and all others, whether functional, mechanical, or parasitical, as they attack the body from the head downwards—a *capite ad calcem*." P. 59.

In accordance with the above advice, the editor, Dr. Rogers, has furnished an Appendix, containing a synopsis of Cullen's Nosology; he has also added some ingenious synoptical tables by Dr. Fletcher, with other useful extracts from various sources.

To the readers of this journal no extracts can be necessary, in order to shew the manner in which the subjects are handled. Perhaps the chapters on Fever, Phthisis, and Diseases of the Heart, may be reckoned the best; but almost every page teems with valuable information. The details connected with Insanity, and some other topics, are so illustrated and enlivened by curious facts from the writings of poets, historians, and philosophers, as to render them highly interesting and entertaining, apart from the important practical matter with which they are interwoven. The style, if not always the most pure and elegant, is nervous and perspicuous; and the colloquial form in which the sentiments were originally delivered, being preserved, imparts an air of ease and freshness which an author's more laboured productions seldom exhibit. Much praise is due to the editor for the exemplary manner in which he has acquitted

himself. He has not overloaded the text with superfluous notes, but has appended just so much as was necessary for the purpose of illustration and to fill up some hiatus. He has also considerably improved the language heretofore marred by the inaccuracies and omissions of reporters; but we will let him speak for himself:—

"No liberties have been taken with the sense, which has in every instance been strictly adhered to. The alterations, numerous as they have been, have been confined to the language, which has been carefully revised throughout. The repetitions and recapitulations incidental to *vivâ voce* delivery have been expunged; the mistakes of the reporter have been corrected; long sentences have been broken up into more manageable masses; intricacies have been unravelled and asperities smoothed; and the greatest pains have been taken to convey information the most valuable, in language the most perspicuous.

* * * He has little doubt, therefore, that the present undertaking will be hailed with satisfaction; and that a due share of support and encouragement will be awarded to the enterprising publisher, for producing this work in a style commensurate with the valuable information it contains."—*Preface*, p. vi.

We join in this reasonable expectation and strenuously recommend the work to all who feel interested in the advancement of Practical Medicine.

The Surgical Anatomy of the Perinæum. By THOMAS MORTON, formerly one of the House-Surgeons of the University College Hospital. Illustrated with Lithographic Plates and Wood Engravings. 8vo. London: Taylor and Walton.

A WORK on the anatomy of the perinæum cannot be expected to offer much that is new in the description of this well-studied portion of the human body. To give the student the best information and directions as to his proceedings in the dissection of this region—the most accurate description in the simplest language—the *detail* in anatomy, as inseparably connected with the *practice* in surgery; the latter giving importance to the former, and the former decision and safety to the latter, is all that can be looked for, and all to be found here.

The plates illustrating the letter-press are well drawn and carefully engraved, and shew with great distinctness the parts to be represented; that exhibiting the side view of the pelvis is, we think, clearer and more to the matter than any we have seen before. We can conscientiously recommend the work, and are glad to find that other equally important regions are about to be treated of by Mr. Morton—we hope in the same simple and useful manner.

MEDICAL GAZETTE.

Saturday, May 25, 1839.

“Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.”

CICERO.

OF WHAT MAY PATIENTS JUDGE?

It is no bad test of advancing civilization that good things become cheap. Another test, or perhaps rather a particular case of the last one, is, that government becomes lenient; so that the sovereign sway is purchased by every one subjected to it at the least possible cost in person, if not in purse. As even the most sceptical confess that government, if not an unmixed good, is at least a necessary evil, they must equally acknowledge that this change is an improvement, and that in spite of infinite grumbling (or through it) the world advances. Three centuries ago, the stake, the wheel, and the gallows, decided every controversy, and it would have been thought as absurd to deny their efficacy, as criminal to doubt their justice. Milder punishments succeeded each other as time moved on; ruinous fines or long imprisonments were first substituted (to the great grief of each *laudator temporis acti*), until, at length, in these ultimate ages, heterodoxy may be broached with safety; and the most unreadable quarto or the smartest pamphlet will rarely

procure the author lodgings at the national expense. After a thousand transmigrations, vengeance has comfortably settled herself in the pen of the reviewer or the epigrammatist. Even the worst and most angry controversialists yield to the irresistible force of the good sense around them, and it would be impossible, in the present age, to get any one to play Calvin to a second Servetus.

Now, as all the institutions of society preserve a kind of harmony with each other, our profession, both in its outward mould and in its manner of practice, has always borne the impress of the opinions current without its precincts. In half-civilized ages, the exercise of power is not restrained by very nice rules of law, and in the days of the High Commission Court and the Star Chamber, we need not be surprised to see the President and the Censors of the College of Physicians constantly sending quacks to Newgate by their own warrant. It was probably thought that such a power was beneficial to the state, and men were unwilling to examine too scrupulously whether it was expressly given in the charter. In small things as in great, the College yielded to the pressure from without, and some minutiae shew as clearly the bent of public opinion, as the shells and weeds cast upon the beach point out the direction of the storm which has thrown them there. Thus in the 16th century we find the College plucking a copper-smith who would fain become a physician, because he could not decline *corpus*; so strongly and so naturally did the stream set in favour of classical learning, at a period when almost every thing worth knowing was shut up in the dead languages!

The practice of the healing art owns the same genial influence of time. No longer are the irons heated for the daily rounds of the surgeons of St. Bartholomew's hospital, as in the days of Pott;

no longer are two or three patients placed in one bed, as in the Hôtel-Dieu of fifty years ago; and the monstrous salivations of the old school live only in memory. The government of the insane, too, has partaken of the general improvement. At a ball given at the Salpêtrière, a couple of years since, the insane women of the establishment crowned the bust of Pinel with flowers—of Pinel, who first delivered them from the system of terror, and discovered that even the mad might commonly be ruled by persuasion.

Perhaps no one carries this medical tolerance further than Dr. Holland, who, in the judicious work * from which we lately selected a subject for comment, has a chapter "On points where a patient may judge for himself."

The first of these points is temperature. This the patient may almost always choose for himself; as it is rare indeed that his sensations deceive him in this particular, or separate the *utile* from the *dulce*. Perhaps in some obscure spots, the old theories, which recommended a hot regimen in febrile diseases, may still linger among the people; but these fancies are immediately dispersed by the first touch of the distemper, which restores every one alike to the wholesome instinct of nature. In the hot stage of an intermittent, Cæsar cries out,

—"give me some drink, Titinius,"
Like a sick girl;

and we suppose that every patient labouring under scarlatina would desire the fire to be put out, and the blankets to be taken off, just as if he had read Sydenham or Heberden. Hence, if an error is committed in such cases, it will be by the bystanders, not by the sufferer. On the other hand, it is just possible that a student fresh from the schools, with an abstract of Currie and

Bateman in his note-books, might push the cool regimen too far, and forget to confine the cold affusion to those cases where the skin is hot and dry; but here again the patient would give a useful lesson to his attendant, and teach him those limits.

"Quos ultra citraque nequit consistere rectum."

In the second place, the patient's desires as to food and drink may generally be complied with. Dr. Holland, however, very properly observes, that "this class of sensations is much more nurtured out of the course of nature than are those which relate to the temperature of the body." Many patients, it is true, while in a state of *quasi*-health, have accustomed themselves to a temperature too high, or to an atmosphere too close or too damp; but what is this to the superfluity of garlic, cayenne, champagne, gelatine, and puff-paste, indulged in by one class; or the gin and eel-pies--the cheap luxuries--of another? Hence this rule is to be received with greater limitations than the first one; and the physician must often delay the food which he does not totally prohibit. The more frequent duty of the practitioner, however, will be to defend the patient from the invasion of hostile niceties sent with friendly intent, which too often, especially in the lower ranks of life, mar the best concerted plan of treatment. According to an article in the *Gazette des Hôpitaux*, provisions of all sorts are smuggled into the Hôtel-Dieu, at Paris, with a zeal and ingenuity worthy of a better cause.

Dr. Holland carries his acquiescence so far as to assert, that "it is not wholly paradoxical to say that we are authorized to give greatest heed to the stomach when it suggests some seeming extravagance of diet." He mentions, in particular, the early stage of recovery from

* Medical Notes and Reflections.

long gastric fevers as affording instances of the advantageous observance of this rule. We have no doubt that this extreme leniency is justifiable, and even necessary in some instances; but, sooth to say, we rather dread the commotion or absolute rebellion that its promulgation will excite among the opulent dyspeptic: the demand for pasties and noyau will, we fear, grow intolerable. We must observe, though, that the indulgence is restricted to cases of actual illness, and does not extend, therefore, to habitual indisposition.

Thirdly, the sick may generally be allowed their own judgment in exertion of body, posture, fresh air, and continuance in bed. Minute and ill-timed interference in such matters often does harm; though, on the other hand, in some chronic ailments of a nervous and dyspeptic kind, it is necessary to urge the patient to use exercise against his inclination, and even when the first trials are seemingly unsuccessful.

Fourthly, the skilful practitioner will often ascertain from the patient the propriety of employing particular medicines, or, indeed, the propriety of employing medicines at all. There is no doubt that idiosyncrasy as to the effects of drugs is more common than is ordinarily supposed, and might often be learned at once if the first examination of the patient were extended to its due length. Again, the extreme nauseousness of many remedies ought to be a sufficient reason for amending their composition, especially when they are administered as tonics. How can a draught which excites nausea be expected to give tone to the stomach or the frame? To which we will add, with Dr. Holland, that when the period of convalescence has arrived, the patient's stomach, weary alike of pill and mixture, frequently demands an entire release from medicine—a sensation as infallible as those by which the ex-

hausted traveller knows that his muscles will bear neither up nor downhill work, but require pure and simple relaxation. On the whole, these varied forms of license indicate a great advance in rational treatment; and put forth, as they are, by so sensible and so experienced a physician, seem to point to the speedy approach of a period when patients of the more intelligent class shall be instructed in the nature of their disorder, and their suggestions regarding its treatment listened to as worthy of attention.

CLINICAL LECTURE

ON

OSTEITIS OF THE UPPER THIRD OF THE FEMUR, SIMULATING HIP-JOINT DISEASE,

Delivered in St. Vincent's Hospital, Dublin,

By J. M. FERRALL, Esq., M.R.I.A.

First Surgeon to the Hospital.

Osteitis of Femur simulating Hip Disease—Mr. Ford's Opinion—First Stage: Diagnosis—Second Stage: Diagnosis—Third Stage—Anatomical Characters.

"DISEASE of the hip-joint," says Mr. Ford, "in every stage of its progress, from its earliest appearance to its final catastrophe, is marked throughout by peculiar and characteristic symptoms." Such, gentlemen, is the opinion of the author of the most original and not least accurate history of Hip Disease that has, perhaps, ever appeared. I have, however, had occasion, more than once, since the commencement of the present session, to call your attention, in the wards of this hospital, to a disease of a nature altogether different from *morbus coxæ*, and yet presenting so many and such striking points of similarity to the latter affection, that the tact and experience of able men have, as you yourselves have witnessed, been foiled by the resemblance.

There is a case of this kind at present under our view; and as there are also two cases of *morbus coxæ* under treatment in St. Patrick's and St. Joseph's wards, I have selected this subject for the matter of our present inquiry.

The disease in question, as far as I have had opportunities of observing it, is met with in an acute and a chronic form. The case at present in the hospital is of

the former character; it will be more convenient, therefore, to commence with the history of that variety of the complaint to which it belongs.

In the acute form the disease commences rather suddenly, and without any previous indisposition observable by the patient. He may retire to rest after the enjoyment of exercise, without even the feeling of fatigue, and be disturbed during the night, or awoken in the morning, with severe pain, referred to the hip and extending to the groin and knee. The pain is so much aggravated by any attempt at movement, that he is rendered perfectly lame; and in severe cases the effort to use the limb may be so very painful that he is totally unable to leave his bed. In the humbler walks of life, however, where little alarm is excited by the mere occurrence of pain, the child may be suffered to struggle to the erect or sitting posture every day for one or two weeks, until his altered appearance become too striking to be overlooked. During this period a state of fever is continually present; the pulse is very frequent; the skin hot; thirst urgent, and tongue coated; the urine is scanty and high coloured; there is flushing, occasional headache, and tendency to vomit; the severity of the pain may be less constant, or may undergo periodical exacerbations, generally occurring towards evening, or in the night. The sleep is disturbed, and accompanied by moaning and evident distress; or in aggravated cases interrupted by delirium. The symptomatic fever is, in fact, generally well marked; and it is worth your remembering that it may run so high as altogether to mask the local disease. I saw a case in Dorset Street, in September last, where delirium was the prominent symptom, and this lesion of the intellect deprived the medical attendant of all information as to the suffering endured by the patient for several days, during which time the real nature of the complaint was not even suspected. Such are the early symptoms of the complaint, which in very acute cases are manifest to the patient or his friends: when the fever is less urgent, and a state of feverishness, loss of appetite and rest, are the general symptoms, the little patient is generally allowed to creep about, although unable to use the limb. If you are consulted at this period of the disorder, two or three weeks from the accession of the attack, you will perhaps be told that perspirations are beginning to be added to the fever, and that he has lost flesh considerably. On inquiry, the pain is referred to the hip about the trochanter to the groin and knee, sometimes as if passing through the joint, and occasionally extending lower down on the outside of

the leg a few inches below the head of the fibula, and accurately defined. If you now proceed to examine the limb, the following will be found to be the phenomena:—

If the patient be in bed he will generally be found lying with the thigh fixed on the pelvis, and inclined towards the mesial line. The comparative length of the two limbs is a point not easily ascertained, on account of the bent position of the one affected; but one knee has sometimes appeared to project more than the other. The loss of power in the muscles about the hip is evident when he alters the position of the limb, for you will observe he accomplishes this object by insinuating the opposite foot under the ankle of the diseased side, and lifting it to the place intended for it. Pressure, even lightly made, on the trochanter or groin, causes pain, and this pain occasionally extends as far as the knee.

In the erect posture there is complete inability to sustain the weight of the body on the affected limb; the knee is advanced, the toe resting on the ground, and the heel supported against the front of the other leg. The pelvis is obviously lower on the affected side; the nates of that side is flattened, and sinks; the obliquity of its lower margin presenting a marked contrast to the horizontal level of the sound one; the muscles of the affected leg are wasted in a remarkable degree. If, while standing before you, he changes his position to either side, or is lifted to the right or left, the sound leg is at once placed in the line of the centre of gravity, to support him; but the affected limb either remains as it was before, or is carried after its fellow by the patient, who instinctively raises it by one or both hands, and places it in its new position.

So far, gentlemen, the phenomena resemble those of acute disease of the hip-joint so closely, that you might easily suppose I had been describing the latter disease; but a more searching inspection will develop other phenomena capable of correcting the first impression, and suggesting a more precise view of the nature of the complaint.

In the recumbent position, for instance, the limb is generally found flexed upon the pelvis. Now this is not the position usually adopted by patients in the early stage of morbus coxæ; and at the period when it does generally occur, the articulating surfaces are engaged to an extent to render the least motion of the head of the femur in the acetabulum a source of severe pain. In the disease we are now considering, if you take the limb so gently in your hand as not to call into action the muscles which connect it with the trunk,

and then press it firmly into the acetabulum, no complaint is made. You can, with the same precautions, cause it to perform all the motions of flexion and extension, adduction and abduction, without the slightest uneasiness to the patient. These are movements which, in true morbus coxæ, would be agonizing in that stage when the limb is found to be habitually in the flexed position.

You will, no doubt, meet with cases of the scrofulous disease of the hip-joint, in which these passive movements can, in the early stages, be performed without any remarkable expression of pain; and therefore this test, taken singly, loses much of its value. Taken, however, in combination with that which I am next to mention, it will assist materially in the inquiry. If, while you cause the limb to perform those passive motions of adduction, abduction, flexion, and extension, you fix your eye upon the anterior superior spinous process of the ilium, you will perceive that this bony prominence remains at rest while the femur moves, and that the head of the latter plays freely in the acetabulum. Now observe what takes place in the genuine hip case, when this manipulation is performed by the surgeon. Every movement of the femur is accompanied by a corresponding change of position of the anterior spinous process of the ilium; the pelvis moves with the femur; and both together now constitute an angular lever, the fulcrum of which is at the acetabulum of the sound side, and the motions of which are performed on the head of the sound thigh-bone. This symptom of inflamed hip-joint has not, I believe, been before described; and I have looked carefully into authors with this view since I first observed it. I have examined a vast number of cases of hip disease, and have not yet met with an exception to the rule of its occurrence. This movement of the pelvis with every motion of the femur, in morbus coxæ, will explain certain cases where little or no pain is complained of by the patient, the motion in many of those instances being only apparent as regards the joint, and the deception being occasioned in the manner I describe.

You can render this fixity of the hip in morbus coxæ more manifest by the following manœuvre:—Place the patient on his back; take one of his ankles in each of your hands, and, while you separate the limbs as far as they can go, observe accurately the two fixed points of the pelvis—the spinous processes of the ilium. You will observe the femur of the healthy side plays freely in its socket; and further, the limb is abducted without any change in

the direction of the foot. On the other hand, the diseased limb carries with it the pelvis; and the latter not only follows it, but is rotated, together with the spine, towards the opposite thigh, in such a manner that the foot is no longer directed forwards, but is inclined towards the middle line of the body. It is difficult to describe this contortion; but as you have witnessed it in both the hip cases now in the hospital, you require no further aid to understand it. In hip-joint disease, in fine, motion of every kind, active and passive, is a source of pain; while in osteitis of the upper end of the femur, although the patient is in the early stage incapable of moving the limb, no pain is experienced when this motion is accomplished by another.

The rationale of these opposite conditions is, I apprehend, to be sought for in the muscles of the parts. In the one case a tonic contraction of the muscles connecting the pelvis and femur is set up, as it were, to maintain the repose of the joint, and prevent the irritation inseparable from its disturbance. In the other case every movement which is painful is caused by the traction of the inflamed periosteum and tendinous attachments adjoining it, when the muscles are called into action. A state of the muscles therefore exists totally different from the former, and is more allied to their powerless condition in acute muscular rheumatism. Passive motion is, in such cases, freely permitted, for the same reason which prevents every active effort being attempted, namely, that muscular action is a source of pain.

If you now seek for diagnostic marks in the erect posture, you will observe that the limb, which is emaciated at the nates, calf of the leg, and lower part of the thigh, presents at its upper third a remarkable expansion; a sudden enlargement occurs here, which gives this portion of the limb a conical figure, the base being placed towards the hip-joint. This swelling is firm to the touch, and is evidently deep-seated; it is, in fact, enlargement and thickening of the bone and its coverings.

The observations already made with respect to the movement of the thigh-bone independent of the pelvis, in the recumbent position, are equally applicable to the erect posture. In the hip case, on the contrary, if you try to extend the thigh on the pelvis, while the patient stands erect, you will observe the pelvis moving backwards every time, and the lumbar spine more curved at the same instant, to accommodate itself to the other parts.

You will by these means have now acquired positive and negative evidence on

which to rest your opinion of the nature of the case. You will have, on the one hand, the existence of a visible and palpable swelling of the upper third of the femur, which marks the existence of actual disease of that bone; and, on the other, you will have ascertained that passive motion can be performed without pain, and independent of the pelvis, to a degree inconsistent with the history of hip-joint disease. Much patience will, however, be required in examining the parts before an opinion is pronounced. Sir B. Brodie, whose tact in the discovery of obscure disease is acknowledged, and whose experience in this class of diseases is perhaps unequalled, expresses himself forcibly on the insidiousness of complaints about the hip-joint. In the present inquiry it is obvious that the evidence by which we are enabled to distinguish disease of a bone in the vicinity of other joints is in a great measure absent here. If the lower end of the femur be enlarged, and pain in the knee be complained of, we are led to the real nature of the complaint by the obvious disproportion between the femur and tibia; but when the upper end of the bone is engaged, all comparison is prevented—in the first place, by its being articulated with a flat bone; and secondly, by the depth at which it lies, as well as the thickness and increasing size of its coverings at this part.

The first stage of the disease, to which the foregoing observations apply, will generally last some weeks, differing in this respect according to the acuteness of the attack.

The second stage is marked by the occurrence of a more irregular fever, preceded by slight rigors, and ending, though not constantly, in perspiration. The countenance acquires an anxious and haggard expression, such as you observe to occur in hectic fever, and the hair has the moist and stringy appearance of that state. The skin is generally hot, sometimes dry, sometimes perspiring; the pulse ranging from 112 to 120; the urine occasionally depositing the lithates and purpures. The tongue may be coated, yet florid at its edge; but I have too often impressed upon you, that the states of this organ will necessarily depend on the condition of internal parts, especially of the digestive tube, to render it necessary to repeat, on this occasion, that, taken as a symptom, no connexion can be established between its various appearances and the existence of any so-called surgical disease.

The local phenomena will, at this period, have undergone some modification. The swelling has increased, and some por-

tion of the integuments have become more prominent, or have acquired a blush of inflammation. Here you may generally expect the formation of matter, although there is neither swelling nor fluctuation in a degree analogous to what occurs in suppuration depending on the soft parts alone. The patient remarks, that when just on the point of falling asleep, he is disturbed by twitching and starting of the affected limb, and his rest is sometimes altogether broken in this manner.

At length the matter is evacuated, either spontaneously or by the assistance of the surgeon, and a remarkable calm ensues. The pain in the hip, groin, and knee, is mitigated; the rest is restored; the fever abates, and the perspirations cease. The appetite revives under this favourable respite from suffering, and the countenance begins to improve, although the pulse may retain its frequency. The inflammation having by this time in a great measure exhausted itself in the organic changes effected in the bone, as well as in the suppuration in the adjacent parts, the morbid sensibility of the attachments of the muscles abates, and the patient begins gradually to be capable of moving the limb to a certain extent without pain.

Although the comparative freedom from pain, and capability of some degree of active motion, characterize this second stage of the complaint, the position of the limb, when at rest, is nearly the same as at first. It is flexed on the pelvis, and the latter is found to be still awry, the ribs and ilium being closer on this side than on the other. The muscles appear to be more at ease in this posture; but, unlike what occurs in the inflammatory stage, they are now capable of moving the limb to a nearly straight position by their own unassisted powers. During the progress to the third stage, occasional accessions of fever and pain are to be expected. The pain is to be referred to the same points—namely, the hip, groin, front of the knee, or directly through the joint. I have heard the same person complain at one time of the outside of knee and upper part of the leg, and at another refer it to the situation of the inner condyle. These exacerbations are sometimes the forerunners of fresh formations of matter; and, when this is the case, are generally relieved by its exit. They may, however, pass off without this result, especially if a few leeches have been applied. When new abscesses occur, the place of pointing is most frequently on the outside of the limb, in the neighbourhood of the great trochanter; although I have frequently seen them at the back of the thigh, below the nates.

The fistulæ arc, for the most part, so indirect and circuitous, that you cannot readily trace them to their termination. The bulk of the swelling is at this time found to be increased; the trochanter being also enlarged in all directions, will appear to ascend higher on the ilium than in the natural state. The remainder of the limb being more emaciated increases the appearance of disproportion between the upper and middle portions of the bone. The integuments of the whole limb are sometimes thickly covered by a long fine hair, such as is occasionally seen in diseases of a marasmal character. The sound limb may exhibit a similar growth, but in much slighter degree.

If you try the effects of passive motion at this period, you will find that although flexion of the thigh on the pelvis is as extensive as before, you cannot now extend the limb in an equal degree. The flexed position maintained by the patient, in order to relax the muscles inserted into parts engaged in the morbid action, has now become habitual; partly owing to a contracted or shortened state of those muscles, in consequence of their long-continued unnatural position, and partly to a mechanical obstacle to extension presented by the increased growth of the femur coming in contact with the brim of the acetabulum. Abduction is nearly as free as in the early stage, but adduction appears to meet also with a firm resistance. The sudden check experienced is easily interpreted by the surgeon, who remembers the hypertrophy of the bone at this part. Some pain is occasionally experienced at the moment when the solid obstacle to adduction is perceived, but it is slight, and referred by the patient to the part struck alone, and not to those distant parts which suffer by sympathy or nervous communication. I must observe, that I have seen a case in which the period occupied in other instances by these changes has passed over without any formation of matter or opening in the integuments.

The third stage of this affection may be said to comprise the period in which the curative process is in progress; the nature of the changes included in this effort of nature, depending, of course, on the degree of injury inflicted by the violence of the primary disease. If many portions of the bone have lost their vitality, their separation from the healthy parts is to be accomplished; and other organic alterations, of a kind not so easily repaired, must have undergone a favourable change before the patient is restored to health. It is in this stage that the powers of the constitution are put to the severest test, and that the disposition to tubercular disease is most likely to be developed.

During this stage the fistulous openings continue to discharge pus. The qualities of this fluid will be found to differ materially at different times, and even at the same time from different orifices. I have seen it remain ill-coloured and fetid for a considerable time, from one or two of these openings, while a more healthy matter was secreted from the remainder. When this has occurred, without being followed by any exfoliation, and has, after a long interval, gradually changed into a more healthy discharge, I have been led to suspect that caries of that portion of the bone corresponding to this peculiar secretion had existed; but as we are not in possession of evidence by which we can determine the question of absorption of dead bone, I cannot assert that the unfavourable condition of the fistula may not have depended on the presence of a loose piece of bone which had gradually disappeared, and not on ulceration properly so called.

The alteration in the discharge alluded to, is sometimes accompanied by increase of swelling and tenderness about the orifice, as well as by some degree of symptomatic fever. It has occasionally happened that these symptoms have been succeeded by the discharge of a portion of sequestrum, generally small in size, and more porous than those which you see eliminated from necrosis in the middle of a long bone. You will, on some occasions, observe this exfoliation to be announced, not by any alteration in the quality of the discharge, but by its total cessation for a few days; and I think I have remarked that the pain and local irritation is then more severe than in the former case.

You may meet with a case where, after the formation of an abscess, the opening will remain solitary for several months; and if the probe be used to test the condition of the bone, you may be foiled by the length and curve of the fistulous canal, and probably obtain no satisfactory information as to its actual state. The swelling may remain undiminished, the only change being that it is less tender on pressure, and that the patient has acquired more power over the limb. The constitutional symptoms, in such a case, may be as stationary as the local complaint. There may be no sweats, nor accessions of fever; but although the appetite and rest are nearly natural, there is not much progressive improvement in the appearance of the invalid. As there may not, during this time, have been any exfoliation, there is no certainty that such a case is one of necrosis; and as I have not yet had the means of ascertaining the anatomical characters of a case presenting exactly the symptoms I have described, I merely men-

tion the facts, and reserve their explanation to another occasion, when an opportunity shall have occurred of tracing the history to its termination.

The cases which I have seen sink in this stage have not done so under the influence of this disease alone. They have died of pulmonary disease. Those which have evinced sufficient vital powers to sustain, and, it may be, to subdue, the force and tediousness of the complaint, are yet under observation. Both these classes include cases in which treatment has been either ineffectual or untried. Another class, in which the attack has yielded to early and active remedies, remains to be spoken of when we come to discuss the treatment of the disease.

This, gentlemen, is nearly the history of those cases which commence in the acute form, and bear, in their phenomena, the closest analogy to inflammation, with necrosis of the long bones, modified, of course, by its occurrence in a part more highly organized, and resisting, therefore, to a certain extent, the destructive power of severe inflammatory action, which, in more compact osseous tissues, occasions the complete and extensive death of the parts.

The cases to which I have hitherto drawn your attention, are, I believe, instances of genuine osteitis, by which I apprehend must be understood inflammation of the cellular tissue by which the bone is pervaded throughout. In those cases, not only the periosteum, but the cellular tissue connecting that membrane with the bone, and that which conveys the vascular network to the interior, become the medium for conducting this formidable disease to the spongy tissue. There are, however, instances to be met with, in which the periosteal covering of the bone is alone affected; but as the latter form of disease does not, as far as I have observed, suggest a different mode of treatment, I do not, on this occasion, deem it necessary to detain you by a separate consideration of the periostitis of the upper third of the femur.

I may, however, remark, in passing, that the swelling is never so great when the periosteum alone is engaged, although the symptoms which simulate so closely disease of the hip-joint, depending, as they do, on the condition of parts connected with the surface of the bone, will generally be present in an equal degree.

Morbid Anatomy.

The anatomical characters of this disease, as far as I have hitherto had an opportunity of investigating the subject, are—1st, simple hyperostosis, or hypertrophy of the bone; and 2d, hyperostosis with death and exfoliation of certain portions

of the osseous tissue. In one case which I was permitted to examine, the state of parts was nearly as follows:—The muscles were pale and wasted; the periosteum and cellular tissue constituted one dense mass, of a consistence approaching the fibrous. The bone itself presented a remarkable increase of bulk, with superficial osseous vegetations or exostoses—some rounded, and others like sharp spiculæ, between which were observed irregular depressions and foramina, into which processes of condensed cellular tissue and vessels had penetrated. In this case the osteitis had apparently occasioned an expansion and increased deposit of the osseous tissue generally, but without any trace of necrosis. There had never been abscess or fistulous opening in this instance.

In another case which I had occasion to examine, and from which several portions of bone had escaped during life, the autopsy disclosed the existence of a new shell, occupying about one-third of the circumference of the upper third of the bone, with large foraminæ leading to a cavity, in which no doubt the small sequestra had resided. The remainder of the circumference and the general aspect of the bone evinced the same degree of hyperostosis which I had witnessed in the former case. The drawings I now present to you exhibit this appearance very faithfully. It was curious to observe, in both instances, the exact limitation of the disease by the line of boundary corresponding to the attachment of the capsular ligament of the hip-joint, while the osseous vegetations sprang freely from the bone close to this line, and projected in a manner sufficient to account for the mechanical check experienced in communicating to the parts the motions especially of extension and adduction.

In the Museum Anatomicum of Sandfort you will find a splendid engraving of hyperostosis of the upper end of the femur. The history of this case is not given, but its characters coincide in many respects, though not in all, with those of the second preparation to which I have called your attention. Mr. Caesar Hawkins, in his valuable lectures on diseases of the bones, states that he has seen more than one case of obscure pain about the hip-joint, with impediment to its motions and suffering of the system, last for many months before the nature of the case was determined, by a fungous tumor being developed. In fungoid disease of bones, Sir A. Cooper says, there is no pain in the beginning. The disease, however, which I am describing is remarkable for setting in with pain and fever, and the bulk of the swelling is rapidly formed.

ROYAL COLLEGE OF SURGEONS IN LONDON.

THE Council of the College having established two studentships in Human and Comparative Anatomy, to be held by each student for the term of three years, at a salary of £100 per annum; candidates for such appointments to be members of the College, under twenty-six years of age;—and the Council having determined that one of such appointments shall take place in June next, gentlemen desirous of becoming candidates are requested to send in their names to the Secretary, at the College, on or before the 24th of June next, when they will be furnished with the detail of the conditions of the appointment.

By order,
EDMUND BELFOUR, Sec.

COLLEGE OF SURGEONS.

GENTLEMEN WHO HAVE RECEIVED THEIR DIPLOMAS.

April 1839.

Winds, S.W. and N.W.

Except the 17th and following day, generally cloudy; rain fell on the 16th, 19th, 21st, and 22d.
Rain fallen, .0475 of an inch.

CHARLES HENRY ADAMS.

NOTICE.

We shall be glad to hear farther from Dr. H.

WILSON & SON, Printers, 57, Skinner-st., London.

* As the French *gras* contains 72 grains, it would be more exact to translate this quantity by gr. cxlv.

† In the original it is *Extrait de Thridace*; but as *thridace* is itself an extract of lettuce, this is probably an error.

ON THE

VENEREAL DISEASE,

*Delivered at the Aldersgate School of Medicine,
March 1839,*

By F. C. SKEY, F.R.S. &c.

LECTURE IV.

*Treatment of Primary Phagedænic Disease
—Mercurial Treatment objectionable—Mer-
cury incompetent to arrest Ulcerative Action
—Treatment by Escharotics in early stage—
Treatment of Secondary Phagedænic Dis-
ease—Iritis—Sclero-iritis.*

ON THE TREATMENT OF PRIMARY PHA-
GEDÆNIC DISEASE.

THE principle of treatment to be adopted in cases of phagedænic disease will materially depend on the stage in which they are first seen. In hospital practice we rarely have the opportunity of treating them during the first; and in private, owing to many circumstances, they are somewhat less intractable. The treatment that is applicable, therefore, in the latter, we can seldom employ in the former, where the advance of the disease has been considerable before the application for hospital aid. I have, in a previous lecture, already expressed my doubts of the possible existence of a true primary phagedænic venereal sore. My belief is, that it becomes phagedænic in virtue of certain constitutional peculiarities. Neither the phagedænic action, nor the disposition, appear to extend far beyond the ulcer in its early stages; and both may be destroyed by escharotics carefully applied to the whole surface. But this treatment is applicable to the first stage only—to the pustule, if it originate in a pustule—and to the sore after the existence of a few days only; and it is

equally applicable to each form of primary phagedænia, but its beneficial influence is most manifest in the severer form of the disease, in which the action approaches to sloughing. The escharotic I prefer is nitric acid—undiluted for the most rapid form, diluted by the addition of an equal quantity of water, for the two first. This may be applied on a pencil of lint twisted round a probe, and followed by spermaceti dressing.

Mercury in any form or quantity, except in single purgative doses, is for the most part highly objectionable. In this stage its influence, though occasionally good, is more generally deleterious; and those cases of phagedænic disease that recover under its administration, recover in spite, rather than in virtue of it. So objectionable does the treatment by mercury appear, that one can hardly persuade oneself how it could ever have been resorted to in this form of disease, had not the ancient custom of treating all diseases supposed venereal, by its means, and deference to antiquity, given their false sanction to its continuance.

The peculiarity of this affection is the propensity to ulceration. Whoever heard of having recourse to mercury in the treatment of any other form of ulceration? We may attack a poison by mercury—we may excite action of the absorbents, or we think we may, by its agency; but I cannot conceive what advantage can be derived from mercury, in a disease which consists of active ulceration. Is it not probable that the process of ulceration, like that of its relative, sloughing, indicates exhaustion in the vessels?—and is the action of mercury stimulating? Does mercury stimulate the vessels in inflammation? Do we resort to mercury in ulcers of the intestines following fever; or in ulcerations of the cartilages of the joints?—or even do we hope to arrest ulcerations of the cornea by its administration. But we may be

told that these are the results of simple inflammation; and what is meant by the specific inflammation of phagedæna? It is a disease that mercury alone can engender. The best authorities that have written, all agree that it may characterize any common venereal sore at any period of its existence. Sir R. Carmichael acknowledges that he never saw it within a fortnight to three weeks from its first appearance. If it be a specific poison, it is one that may be generated by the possessor, as well as acquired from another, whether possessing it or not, and owing its peculiar characters to the constitution of the person possessing it. No one doubts that its ravages are most severe and uncontrollable in weakly and cachectic habits. Why, then, should it be treated with mercury? Neither theoretically nor practically do I observe, with certain limitations, any thing but evil from its administration in phagedænic disease.

If, after the first application of the nitric or diluted nitric acids, no advantage be gained—if the sore do not clean and manifest a disposition to granulate, the application may be repeated. Should it fail a second time, the treatment by escharotics should be laid aside, and the sore, unless of the more destructive kind, be left uncontrolled for two or three days, when it will assume the aspect of the disease which is generally first presented to us for treatment. That which we should now adopt will depend on the pulse, as an indication of the general powers: if full and hard, we may take some blood from the arm, and follow up the treatment by antimonials, which I prefer in the form of the solution of tartrate of antimony, 2 grs. to the quart of lemonade; but we shall rarely be warranted in having recourse to the lancet, the character of the pulse being generally full, but soft, though accelerated.

If the sore exhibit the white surface, it will prove slow but resolute in its progress; if a darker surface, it will be more rapid and destructive. In the former case, you may leave it untreated locally for a few days, enjoining simple ablation with warm water, and simple dressing of cerate spread on linen, if on the glans or inner surface of the prepuce, the glans being more generally the seat of this form of sore. We then commence a series of experiments on the sore, which should be seen daily. These consist in the endeavour to ascertain what form of local application is most agreeable to the disease; and of such remedies we may try black-wash or yellow, weak dilutions of nitric acid, Peruvian balsam, oxide of zinc ointment, citron ointment, solutions of nitrate of silver, and such stimuli. A low

diet, though occasionally desirable, is not commonly so, nor is much to be gained by internal stimuli, unless the patient has been accustomed to them. These means will generally succeed in wearing out the disease in the course of from one to two months, unless mercury has been employed, for then the period required will be longer, even to the extent of four or five months.

The treatment of secondary phagedænic disease also should be modified by the state of the pulse, and by the activity and extent of its progress. If eruption and sore throat appear contemporaneously, or nearly so—if the eruption be extensive and early in its appearance—either during the ulcerating or cicatrizing stage of the primary ulcer, we may expect the case to present itself in a formidable character. If the eruptions appearing about the face and neck are few in number, and extend at a longer interval of time—if the sore throat be partial, and do not advance to the ulceration of the surface, we may reasonably expect that the disease will be controlled by simple means. A certain amount of fever will always attend it, and for which the antimonial solution above recommended may be administered. If the febrile symptoms are considerable, blood may be taken by venesection, in a quantity proportionate to its effect: I conceive, however, about 10 oz. to be the maximum. The advantages of moderate depletion have been dwelt on by Sir R. Carmichael, and there can be no doubt that they are often considerable. But you must always keep in view the asthenic nature of the disease you are treating, and be careful that you do not deprive your patient of resources the possession of which are indispensable to his restoration. You rather treat the symptom, than the disease, and this object may be generally effected by abstracting from 8 to 10 oz. of blood, and that only when the fever is considerable. At the expiration of three or four days devoted to the treatment by antimony (not, however, to be administered to nauseate the stomach), the bichloride of mercury may be given in compound tincture of bark, to which the compound tincture of camphor may be added, should the mercury affect the bowels. I usually give one-twelfth of a grain thrice a day, with a drachm of the bark to each dose. After the slightly depressing influence of the antimony, the effects of this medicine are often most excellent, especially when coupled with improved diet and exercise in the open air, in mild weather. Nocturnal pains in the limbs will be generally mitigated by either the extract of cicuta or compound ipecacuanha powder in doses from 5 to 8 or 10 grains, the half of which may be repeated in the day time.

A gargle of distilled vinegar, diluted with two, three, or four parts its quantity of water, may be used frequently in the course of the day. I order it every two hours, and to be employed as hot as the patient can bear it. Some prefer muriatic or nitric acid gargles, but it is really of little moment.

The general disease will feel the effects of these remedies most unequivocally. They may often be persisted in till the patient is convalescent; more frequently, however, without apparent cause, the disease again advances in full force. The general aspect becomes more asthenic, the pulse is rapid, very compressible and weak, although it may be more or less full; the pharynx ulcerates; the eruptions papular, pustular, and tubercular, return with renewed energy, and extend over the whole surface of the body, commencing more generally on the back and shoulders; the thick crusts of rupia, prominent and cachectic, form more frequently on the face and arms, some of which attaining a small size only, separate and disclose wide spreading ulcers underneath, and of these we have often as many as from ten to twenty of various sizes in various parts of the body. Some may be healing, others already cicatrized, while the majority extend, secreting a whitish somewhat tenacious matter. I believe it is perfectly useless to treat these ulcers during their ulcerative stage, and that it is far preferable to cover them with bread and water poultice or simple cerate dressing, until that action has exhausted itself spontaneously, or been held in check by the constitutional remedies. In this stage I should suspend even these for two days, excepting the Dover's powder or cicuta, and then commence with the hydriodate of potash in the bark, or combined with large doses of sarsaparilla as before: four or five grains may be ordered to a drachm of the tincture, three times in the day, with meat diet. If with sarsaparilla, the dose of the latter should be large. I have no faith in moderate doses of this highly-prized drug; and, except that it often improves the appetite and forms a moderately good antidote to mercurial action, I cannot say that I deem it by any means a valuable remedy. In this state, I have found great benefit to be derived from large doses of Dover's powder, to the extent of ten or fifteen grains, night and morning, and I have occasionally, during the granulating stage, employed much larger doses with advantage. The state of the eruption I have described is not usually accompanied by the severe form of ulceration of the pharynx. When that symptom exists, it is, I think, more usually found alone, and it will prove a

sufficiently intractable enemy, to require all the resources of the surgeon. The whole surface should be lightly touched with the nitric acid, diluted, according to circumstances, with two, three, or four times the quantity of water. It may be applied by means of lint twisted on a long probe or director. This may be changed for nitrate of silver, ten or twelve grains to the ounce of water. Sometimes the ulceration will be arrested by fumigations of the red sulphuret of mercury, employed each morning. But so capricious and intractable is this form of disease, and so uncertain our remedies, that after adopting systematically every agent that anxiety and ingenuity can devise, it may extend to the destruction of our patient, who is at length worn out by long draughts both on his circulation and nervous system; or on the other hand, the throat or the sores may almost suddenly assume the aspect of health, on the return to some remedy which had been previously laid aside as useless.

The examples of phagedænic disease are sufficiently numerous in the metropolitan hospitals; and for the purpose of showing you the peculiar intractability of it in its more confirmed stages, its fitfulness, and its deeply-rooted constitutional character, I will direct your attention to a single case; not, observe, on the ground of its peculiarity, but of that of its usual conformity with the train of symptoms that daily characterize it.

Thomas Morley, aged 24, was admitted into St. Bartholomew's Hospital on the 12th of June, 1836, with a papular, pustular, and tubercular eruption on the back, chest, and arms. He had likewise sore throat, affecting the whole palate, and nocturnal pains in his shoulders and lower limbs. He stated that he had acquired a sore on the fossa of the glans, eight months previously, which appeared within a few days after intercourse, and which extended during a fortnight, for which he was subsequently twice salivated. During the first salivation, which was very severe in its influence on the system, the sore rather progressed, and bubo appeared in the groin. The second resort to mercury rather benefited the sore, which slowly healed. As to the character of the sore I could obtain no satisfactory information; there remained, however, an extensive cicatrix, but no hardness nor depression. The condition of the gums bore ample testimony to his statement regarding the mercurial treatment. I ordered him a mild aperient, and on the following day the

Tinct. Cinchonæ c. ʒiiss.; Hydrarg. Oxymer. gr. j. Sumat ʒj. ter indies.

I put him on milk diet, but gave him strong broth daily. At the expiration of a fortnight, his improvement being very questionable, and his nocturnal pains somewhat on the increase, I gave him five grains of hydriodate of potash three times in each day, first without and then with the tincture of bark. Under this treatment he progressively improved during three weeks, in every respect except one, viz. the throat. An ulcer formed on each tonsil, of a foul and phagedænic character. These were fumigated with cinnabar each morning with some advantage, and cleansed with a gargle of tincture of myrrh in camphor mixture. About the middle of August, without any apparent cause, his symptoms made a sudden and rapid advance. Many of the pustules formed large and prominent crusts, while others degenerated into circular patches of ulceration. I now ordered him, for three days only, five grains of blue pill, night and morning, with two grains of extract of henbane to each dose. I then renewed the pill for three days longer, but his health was manifestly sinking considerably, and he was losing flesh rapidly; his throat at the same time improving. I then returned to the bark and hydriodate, and gave him porter daily. From this date to the middle of September his symptoms alternated between bad and worse. He then appeared to derive some advantage from extract of cicuta, with sarsaparilla, in large doses. An attack of diarrhœa compelled me once more to change the treatment; and at this date, the 20th of September, several ulcers on his legs and back, which had attained a considerable size, were yet extending; they were poulticed and dressed after a variety of forms—black wash, yellow wash, cinnabar fumigation, and Peruvian balsam, being employed in succession. Internally he took nitric and muriatic acids, sulphate of quinine, wine, hydriodate of potash, sarsaparilla, each with a brief but most transient benefit. On November 3d, his body was covered with sores, varying in size from that of a finger's nail to the palm of the hand. His strength was so far reduced that he could not move in his bed, and his appetite so impaired that he nauseated food of every description. I then requested Mr. Earle to see him, to whom I stated that I would consent to adopt any treatment except that by mercury. He said he could suggest no other, but recommended that, which I declined. Having exhausted the ordinary and extraordinary resources of medicine in such cases, I returned to the bark with nitric acid, and under its influence, strange to say, his appetite returned, the ulcers healed with rapidity, and on the 22d of the month he left the hospital for the country, quite convalescent.

In the more chronic forms of phagedænic disease the tunics of the eye are frequently involved. It is very rarely that the iris is affected singly, or even primarily, but it is generally more or less inflamed. The character of the inflammation is closely allied to the rheumatic, and it is not therefore surprising that the fibrous sclerotic is early involved. The inflammation of the sclerótica is not generally very severe, and the iris may be even less so.

But the latter membrane, on the ground of its important relations and greater susceptibility of injury from inflammation, is the object of the first interest. The intensity of the iritis will determine the treatment to be employed; and this, if not severe, will depend on the constitutional health of the person. If the intolerance of light be great, the pupils shew great tendency to permanent contraction. If the aqueous humour exhibit extreme turbidity—if the pain be chiefly confined to the ball of the eye, and subject to no remission, more especially at night—then the iris is seriously affected. It is then of no moment what may have been the cause, or what may be the probable injury to the health from the employment of mercury; for mercury is our chief and most important resource, and it must be administered in doses both frequent and large.

In phagedænic disease, however, this degree of inflammation is rare, the iris, as I have before observed, being secondarily affected, and that only in a minor degree. We generally find it unattended with considerable intolerance of light; the aqueous humour moderately turbid; the pupil but moderately contracted, and in a greater or less degree obedient to the influence of light on the retina; the pain not confined to the globe, but diffused around the brow; and, what is equally important, we find it distinctly subject to nocturnal exacerbations. In this state it may remain for many days, or even weeks, without the eye undergoing any considerable change. Here the sclerótica is primarily, the iris secondarily affected. The participation of the former may be determined by its pink colour seen through the conjunctiva. The redness may become more marked around the circumference of the cornea: it may even appear in the form of a tolerably distinct and broad circle, but diffused over a considerable extent of surface; but that is of no moment, so long as the mild train of symptoms exist which are attendant on subacute inflammation of the iris. This disease is often termed "syphilitic iritis," and the name alone appears to carry with it the warrant for the fullest exhibition of mercury, which is deemed no less the antidote to syphilitic

poison than to iritis itself. But the forms of inflammation that attack the iris are various in degree as well as in character. It may be a simple tonic or an atonic inflammation. It may be syphilitic, or rheumatic, the latter being not unfrequently the product of mercurial action. I shall not stop to inquire whether the disease I have been describing appertains to the mercurial, or to the rheumatic, or to the phagedænic, or even whether it be or be not venereal; it is sufficient for my present purpose that I observe it to occur in a constitution impaired by long-continued disease and by severe treatment, and that the general condition of the person is eminently asthenic. This is no case, therefore, for sudden and depressing doses of mercury, or for copious depletion; the case is rather to be treated constitutionally, so long as we can detect no organic deposit on, or change in, the structure affected. Such form of inflammation will be more readily brought under control in some cases by colchicum and Dover's powder; in others, by bark and general tonics, than by the wasting effects of that mineral which, employed in the treatment of the acute and tonic forms of iritis, presents one of the most valuable resources of modern medicine, and whenever we find the less asthenic constitutional and the severer local symptoms predominate, we should not hesitate one moment in having recourse to it.

Among the important agents to be reserved for the last stage of phagedænic disease, let me not fail to do justice to mercury, which may then often be employed with the greatest advantage; and this treatment is not less (perhaps rather more) applicable, to that class of cases which owe their early virulence and intractability to excessive mercurial action. It should, however, be employed with caution. I do not mean to say that any danger attends its employment in moderation, but I am very certain that either good or great evil, will result from it. The constitution may be brought under its influence by five-grain doses of blue pill, and one-fourth of a grain of opium, night and morning; and if advantage be not derived when the gums are swollen and mercurial fœtor is produced, which will probably be effected in the course of five or six days, you ought not to push it on to positive salivation, and much less to ulceration of the gums and swelling of the tongue.

When the ulcerative stage has ceased, the sores may be treated with the oxide of zinc or the citron ointment. The Dover's powder will promote the growth of granulations, and the sores may be

treated on the simple principles which guide us in the management of common ulcers. Granulations may be repressed by nitrate of silver wash, or dry lint; and in the last stage of these sores you will often derive important aid from the application of the balsam of Peru.

If these remedies, topical and general, fail, there remains one remedy to which medical men will have, I imagine, little objection to resort to, and it is, perhaps, the most valuable of any to a metropolitan surgeon—and that is, change to a purer air. It is in towns alone that phagedænic disease presents these formidable characters; and it is on the victims to confined and unwholesome air—to crowded rooms, bad diet, and depraved habits of life—that its fury is directed. Country air is the peculiar resource of the practitioner of large towns, and which, if resorted to early, may afford some feeble antidote, however meagre, to the train of consequences that are often otherwise uncontrollable.

OBSERVATIONS

ON

COMPLICATED SURGICAL INJURIES,

INCLUDING GUN-SHOT AND OTHER WOUNDS.

By RUTHERFORD ALCOCK, K.T.S. &c.

Late Deputy Inspector-General of Hospitals with the Auxiliary Forces in Portugal and Spain.

(As delivered in his Lectures at Sydenham College School of Medicine.)

[Continued from p. 304.]

V.—INJURIES COMPLICATED BY LESION OF BLOOD-VESSELS.

Power in the arterial trunks of resisting or eluding violence.—Case of ball passing between the artery in the popliteal space and the femur, which it fractured.—Incomplete division of arterial trunk not necessarily fatal by primary hæmorrhage.—Case of lacerated carotid, secured twelfth day with success.—Case of hæmorrhage stopping spontaneously.—In operations for wounded arteries the tourniquet to be avoided.—Tables shewing in 1350 wounded the proportionate duration of treatment in different classes of injury, and the mortality.

In considering the nature and treatment of injuries in the immediate vicinity of arterial trunks, it must be borne in mind that the tough and elastic structure of the large arteries enables them to clude, and even to resist, a great deal of violence, without the vitality or continuity

of the parts being destroyed. Of this a good example was furnished by the case I related to you (see pp. 202-3), where a missile which had occasioned the most extensive laceration of soft parts, and the crumbling of portions of the bone beneath the artery, yet seemed only to have bruised the latter, and apparently not in a degree sufficient to destroy its vitality. Before concluding these remarks on injuries of the extremities, in reference to fracture and lesion of blood-vessels, I will relate the following case bearing upon the feature last described, and of great interest, as one of the very few cases of longitudinal fracture ever met with, presenting no crepitus or obvious signs, and allowing the patient after the injury to stand upon it.

Fracture of Femur through popliteal space, the Artery escaping injury.

S. Bagley, æt. 40. In March 1833, when but a few yards distant from one of the enemy, saw him level his musket, and while calling to him not to fire, received the contents of the piece through both thighs.

When brought to the hospital in Oporto some two or three hours after the receipt of the injury, he stated that profuse bleeding had taken place. He was in a low shivering state, suffering from spasms of all the muscles, and with a trembling hemorrhagic pulse. He was evidently labouring under violent constitutional disturbance.

The right limb during one of the spasms appeared to me somewhat distorted, and gave rise to a suspicion of fracture. On examination, however, I could neither move the lower part of the limb upon the upper, nor could I detect any crepitus. He had also walked across the room.

The hæmorrhage was described to have spouted out in a stream, and the direction of each wound just above the condyles, the ball passing apparently behind the femur, across the course of the artery as it winds into the popliteal space, led to some suspicion that one or even both popliteal arteries might be injured.

The wound was rapidly followed by a severe attack of delirium tremens, and the patient, a hard drinking man, and very unfavourable subject for a severe

injury, died on the fifth day. Slight hæmorrhage occurred occasionally.

Post-mortem examination six hours after death.—On passing the finger into the wound of the right limb, I felt the surface between the condyles had been grazed by the passage of the ball, which consequently had traversed under the artery and vein. On proceeding further I detected a fracture; but even then I neither could produce any crepitus, nor move the upper and lower portion (if they may be so described) upon each other. Finally, cutting away all the muscular attachments, a nearly longitudinal fracture, merely diverging a little obliquely, higher up, was laid bare, extending from the base of the internal condyle to the lower portion of the upper third of the femur. The fracture was moreover irregular in figure, the different parts locked or dove-tailed into each other; so that even when thus deprived of all support, the motion was but very trifling. The periosteum in a great part of the length of fracture remained entire.

In the left limb much less mischief had been done; the ball had passed over the artery and vein, and through muscular and tendinous fibres only, to its exit.

The liver was unhealthy in colour, and shewed marks of inflammation on its surface.

This is a case proving that the eye may furnish truer data than the hand sometimes in fracture; and further, I trust it will impress upon your minds one fact of importance, viz. that in reference to the diagnosis of fractures, *negative* evidence must not be implicitly relied upon; it was here very complete, and notwithstanding, the bone, on which the whole weight of the body is thrown in walking, was very extensively fractured.

Such complications of gun-shot wounds as lesion of blood-vessels, &c., are not of course confined to the extremities; but I have considered them first in such situations, because there is an alternative, and the life of the patient may generally be saved, by amputation, if all other means fail. In the face, throat, and neck, when cases of secondary hæmorrhage occur, there is no such alternative, and it will rarely happen that ligature any where but on the artery, at the point of its rupture,

will succeed in stopping the flow of blood. It is generally held, that an incomplete division of a large arterial trunk, whether by shot or incision, will prove instantaneously fatal if no effective means be taken to prevent it; occasionally, however, a very striking exception may occur. One case of this nature I will shortly relate to you, both because I do not know of any similar case on record, and on account of its forming an excellent illustration of the great difficulties, presenting under such circumstances, which may be overcome with a successful result.

In one of the actions in Portugal—it was during a vigorous attack made by the Miguelites, in March 1833, on a part of the lines of Oporto, defended by the Scotch battalion—I observed among the wounded one evidently in danger, lying in a house near the road where they were temporarily placed during the heat of the fight. I examined him; he had apparently received a fatal wound in the face and neck. A musket-ball had entered the right cheek, on a level with the alveolar process of the last molar tooth, and passing downwards, made its exit in the neck of the opposite side, just above the clavicle, grazing the shoulder afterwards.

He lay totally insensible, labouring under the effects of concussion, with stertorous breathing, possibly also suffering from the loss of a large quantity of blood, although there was little about him where he was lying.

He was conveyed to one of the hospitals under my charge in Oporto, where I saw him the next day, considerable tumefaction having come on, both of neck and cheek: he had recovered from the immediate effects of concussion, and was sensible.

On the third day after the action there was already considerable discharge; and on the fourth the sloughs began to separate, and a portion came away from the neck, which then presented a clean-looking wound.

On the fifth it was reported that there had been a little bleeding from both the wounds twice the day previous, and the discharge of matter from the neck was very abundant.

On the seventh, hæmorrhage to a considerable extent returned from the wound in the neck; the blood partly venous and partly arterial: he was plagued with a troublesome cough.

On the eighth I found there had been two or three ounces of blood, chiefly arterial, discharged during the night.

On the ninth a similar report. He had a recurrence of slight hæmorrhage the previous afternoon; none during the night; but again on the ninth evening hæmorrhage to the extent of two or three ounces from the wound in the *cheek*. "Pulse quick, and rather wiry; difficulty of swallowing great; brings on cough. Patient very obstinate and unmanageable; will not attempt to swallow any medicine."

Tenth and eleventh, occasional slight returns of hæmorrhage, generally brought on by a fit of coughing. Pulse very languid.

On the twelfth day, about noon, while I was in the hospital, hæmorrhage returned, and with great violence. Finding pressure on the carotid artery effectually stopped it, and seeing the patient's life in imminent danger, I determined to cut down in the direction of the wound, to ascertain if any opening existed in the common carotid—though I scarcely could believe this to be possible, seeing the repeated and trifling hæmorrhages which had arisen, and at all events to place a ligature on the trunk, and endeavour thus to arrest a hæmorrhage for which there seemed no other remedy.

Having wheeled the bed round to the light, his shoulders and head gently raised, I made an incision over the inner edge of the mastoid muscle, from about the level of the cricoid cartilage to within a short distance of the sternum. I laid bare the edge of the muscle, which could be distinguished, but found it so firmly bound down by lymph and hardened cellular tissue, that neither with my nail nor the handle of the scalpel could I move it a single line, or separate it in the least degree from the parts below. This I effected, therefore, with the scalpel; but instead of finding the smooth cervical fascia, and marking the omo-hyoideus passing across, there was nothing but diseased cellular tissue, condensed by the lymph thrown out in the inflammatory process. I felt the artery feebly pulsating some time before it could be seen, which was at last accomplished after removing a large fibrinous coagulum. The artery was then exposed at a considerable depth from the surface, and a lacerated opening of nearly half an inch in extent was

distinguishable in the canal of the carotid artery. The vein also appeared, though less distinctly, to be lacerated.

I endeavoured to pass a blunt needle under the artery, but found it so firmly embedded in the surrounding diseased structure, that by the edge of the knife alone could I succeed in detaching it. On the side next the trachea it was equally firmly bound; and in the endeavour to separate it a small incision was made into the windpipe; a little blood escaped at the same moment, the air was violently forced out, and he sank to appearance, in almost the same instant, into a state of *articulo mortis*. He seemed to be dying without an effort or a struggle, and for a second I was paralyzed by the conviction of the hopelessness of any attempt to save or restore him; for although it must always be a painful thing to a surgeon to see a patient die during an operation commenced in the hope of saving his life, I had too well considered the case, and convinced myself of the propriety of the operation, and that I had performed it with all the care in my power, to be paralyzed even for an instant by any other feeling than the conviction of his death being at hand. The next moment's reflection suggested the expediency of concluding the operation. I therefore passed a needle through the wounded part of the trachea, and brought the edges together by a thread; secured the artery above and below the laceration, and brought the integuments together by suture and strapping. He began to rally before I had concluded, and was able to speak and answer a question put to him. He breathed perfectly freely, and there was no oozing of blood from either wound; pulse was small and quick.

After this there was no return of hæmorrhage, either from the neck or from the wound in the cheek; and although a few days subsequent to the operation he had a sharp attack of fever, both wounds did well, and he recovered entirely as regarded the neck before he was sent home. Some exfoliation was still going on in the lower jaw; and I told him to shew himself to Mr. Guthrie, who afterwards, in the Westminster Hospital, performed an operation for the removal of a portion of necrosed jaw.

I could not possibly select a better case to prove to you many of the

peculiar features of this kind of injury, and the operations they occasionally require; nor to impress upon you the principle, that no difficulty, fear of failure, or rather of moral responsibility, should prevent a surgeon's operating, whenever by that step he offers a chance of safety, where life must otherwise be certainly lost. A motto of ancient chivalry should be that of a surgeon—

“Fais ce que doy adient que pourra!”

By this self-devotion, or courage, if you will, I have seen many lives saved which otherwise would have been certainly lost; and here is the advantage of the labour you are now giving to obtain accurate and extensive knowledge; its acquirement not only insures the best measures suggesting themselves to you in difficult circumstances, but it gives you courage to adopt them in extreme cases, whatever may be the difficulties or danger.

Some rare instances will occur where a smart and often-recurring secondary hæmorrhage, supervening in these complicated injuries of the face and throat, stops spontaneously after a time. The following is an instance—rare exception, however, and never to be counted upon as probable.

Compound Fracture of the Bones of the Face.—Loss of Power of Mastication and impaired Articulation.

Series of the 5th of May.—Joseph Welsh. A musket-ball entered the right superior maxillary bone at the centre, and, passing obliquely downwards across the face, came out at a similar point of the inferior maxillary, crumbling and crushing teeth, bones, and flesh, in its course, to a more than usual extent. On the 4th and 5th day hæmorrhage came on, and on the 5th to such an alarming extent that thoughts were entertained of taking up one or both of the external carotids: from what branch the blood poured it was impossible to decide. The hæmorrhage proceeded from both wounds, and the swelling of the tongue and mouth was too great to allow any examination. It stopped spontaneously, and did not again recur.

At the end of four months there was very little external deformity, and on the left side four good molar teeth were left, with which he would ultimately be able to masticate, although not at that period. He could open his mouth to

two-thirds of its natural extent. After a somewhat tedious exfoliation, a good union of bone was effected.

Let me warn you against the use of the tourniquet for the suppression of hemorrhage, during the performance of an operation to secure a wounded vessel. Let pressure be made on the trunk of the artery alone, by the thumb or fingers of the assistant, without encircling the whole limb. This kind of pressure was changed by the assistant in a case where I was operating for wounded radial artery near the bend, and instantly and continually the wound was filled with venous blood, from which it was impossible to clear it for more than an instant.

I shall here conclude my remarks on these (certainly the most formidable) complications of fracture and of gunshot wounds generally; formidable both to the patient and the surgeon. I trust these observations in connexion with the

cases I have related will serve to make you acquainted with the nature and proper treatment of such accidents, and when they suddenly occur in practice hereafter, prevent your being taken unprepared.

I shall next proceed to the consideration of another class of most important and complicated injuries—those of the head and spine. The previous lectures having been much devoted to the general characters and course of *gun-shot* wounds, the accompanying tables, made out with great care, to shew the duration of treatment for wounds of the various classes, and their mortality from the first to the sixth month, may serve to complete the view. I am not aware that any similar attempt has been made to demonstrate the proportionate duration of treatment and ratio of mortality; and the subject seems to me both practically important and interesting.

General Return of Surgical Cases treated, and capital Operations performed in the General Military Hospital of St. Elmo, San Sebastian, from 5th May, 1836, to June 10th, 1837—a period of thirteen months.

INDUCTION OF PREMATURE
LABOUR,

WITH REMARKS.

To the Editor of the Medical Gazette.

SIR,

IN the MEDICAL GAZETTE for the 8th of September, 1838, you were kind enough to favour me with the insertion of a very interesting and important midwifery case. By referring to it, you will find that it was one where I was under the necessity of inducing premature labour, in consequence of a considerable contraction or deformity of the pelvis; and the mode I adopted for accomplishing this purpose, so far as I can ascertain, differed from that of any preceding obstetrician, inasmuch as it was effected by the administration of the secale cornutum, to the exclusion of every other means. The previous history of the patient was pretty minutely given; but, lest some of your present readers may not have seen the case, nor have any convenient opportunity of seeing it, I will briefly state a few of the particulars, that they may the more fully understand the propriety of the practice pursued in the one which follows:—

The patient, Mrs. R. Brown, of Tylefield, was 29 years of age, and had borne eight children. Her first labour was comparatively easy, but every succeeding one became more difficult and dangerous, in consequence of the pelvic bones gradually encroaching on the cavity and outlet of the pelvis. The three first children were born alive; the fourth required the forceps, and was dead; the fifth, though remarkably small, likewise required the forceps, and was born in a state of asphyxia, but, by proper treatment, recovered. In the sixth I attended her, and on a careful examination found that the conjugate diameter of the pelvis did not exceed three inches, so that after a tedious and most painful labour, being unable to deliver her with the forceps, I was obliged to perform embryotomy, after which she was delivered of a very large male child. She recovered well, soon afterwards became pregnant, and allowed herself to go to the full period of gestation. A surgeon attended her, who, finding it impossible to deliver her in the natural way, or with the for-

SIXTH MONTH.

ceps, was obliged, with the assistance of another surgeon, to break down the head. From the effects of this confinement, she recovered slowly, and was ever afterwards afflicted with an extensive vesico-vaginal fistula. Independently of her misfortune and her former sufferings, she again was pregnant, and consulted me in the fourth month, when I advised her, for her own safety, and as the only chance which remained for the preservation of her infant, to have labour induced in the seventh month of utero-gestation. She agreed to this, and I was fortunate enough to accomplish it by means of the following:—

R Pulv. Secale Cornut. \mathfrak{zss} . Aq. bull. \mathfrak{zxxiv} . Syrupi Simp. $\mathfrak{3j}$. M.

Two ounces of this infusion were exhibited every third hour, and after this quantity was finished, other two drachms were prepared in the same way, and given at shorter intervals; so that altogether she took six drachms of the medicine, and the time occupied from the first administration to the birth of the child, which was alive, was thirty-nine hours and fifteen minutes.

Since the publication of the case, it has afforded me much pleasure to observe, that Mr. Heane, a gentleman of considerable experience, in Gloucester, has been induced, by reading my paper, to adopt the same practice with a patient (Harriet Sander, æt. 43) who had been pregnant thirteen times, and had six of her children still-born, five of them having been destroyed by the perforator. The preparation of the drug, and the mode of administration, were the same as I had employed, and I am happy to say that it was attended with complete success, in the short period of twenty-two hours. The details of this excellent case are given in the *MEDICAL GAZETTE* for the 26th of January, 1839.

Mrs. R. Brown, of Tylefield, having again nearly completed the seventh month of utero-gestation, on Monday, the 29th of April, I commenced the operation of inducing premature labour. The bowels were freely evacuated in the forenoon with the pil. colocynth. comp.; and at 10 o'clock p.m. she had \mathfrak{zss} . of the pulv. secale cornut., prepared as in her former case, administered in the same doses and at the same intervals of time. When twenty-four hours had

elapsed, little effect was produced, with the exception of a feeling of weight about the loins, and a slight tendency to bearing down. No impression was made on the os uteri, nor had there been any thing like distinct pains. On Wednesday, the 1st of May, at twelve o'clock meridian, there was still little alteration; and, as there had been no motion of the bowels since Monday, she had a couple of colocynth pills, which operated mildly. Her infusion being done, I divided an ounce of finely pulverized secale into sixteen powders, and ordered one to be taken every second hour, after being macerated in boiling water for twenty minutes. Slight uterine pains followed the administration of the second dose, and at 8 o'clock p.m. the os uteri was dilated sufficiently to admit the point of the finger. I made no attempt to ascertain the presentation, lest the effort should separate the membranes, and thus interfere with the intended action of the medicine.

Thursday, 11 o'clock a.m.—During the night she had frequent pains, but only attended with slight bearing-down; and on examining, I now found the neck of the uterus more obliterated, the os uteri softer, and dilated above an inch; the membranes felt distended with the liquor amnii, but the child had not yet entered the pelvic cavity.

9 o'clock p.m.—Has taken all the powders, and is much in the same way as in the morning. She feels the motion of the child very lively. Seeing that labour was not likely to be speedily effected with the quantity of medicine she had taken, I infused ten drachms of the secale in twenty-four ounces of boiling water, and of this she took two ounces every third hour.

On Saturday, at 11 o'clock a.m., there was little further perceptible change, and I almost despaired of accomplishing the desired object by the efficacy of the secale cornutum alone. As she had taken two ounces and six drachms, I considered it would not be proper or justifiable to push the medicine further, without having the opinion of some other practitioner on the subject. I therefore called in an experienced medical friend, who examined minutely into the state of the patient's feelings, in order to ascertain if she found any ill effect from having taken so much secale. Her strength being good, her pulse

regular and calm, her appetite not at all impaired, and as she said that she did not experience the slightest inconvenience, there being nothing to contra-indicate the practice, with the view of giving the medicine a complete trial we agreed to prepare other ten drachms as before, but to give it in rather smaller doses, and at intervals of two hours. At four o'clock P.M. she commenced taking it as prescribed, and in a few hours was conscious of stronger pains and more bearing down. By seven o'clock on Sunday morning this infusion was finished, but owing to my being engaged with two other accouchments I was prevented from seeing her till two o'clock P.M. Pains had then left her for some hours, though, on examining, I found the os uteri very low, dilated to the size of a crown-piece, soft, and yielding readily to the fingers. The presentation, which was a footling, could be easily made out through the membranes, which protruded from the os uteri. Since I saw her last she had enjoyed a most refreshing sleep, and had taken her breakfast heartily.

It was now evident that a termination of the labour could not be far distant, and that it only required a regular and quick succession of pains to accomplish this much longed for event. I waited for two hours, trusting that nature would soon establish her own process, and thus, without further interference, effect the expulsion of the child; but not the slightest symptom of a pain occurred, and the patient seemed anxious that I should do something. From the generally relaxed state of the parts, and the progress she had made, I considered it likely that another dose of the secale cornutum would in all probability excite the uterine contractions. I infused two drachms, and gave her the third part of it at four o'clock. In fifteen minutes a pain ensued; in twenty minutes another; and at the half hour she had a good bearing-down pain. They now continued regular and effective. At five o'clock the membranes protruded from the vulva; but I endeavoured to prevent them giving way as long as possible, in order that the liquor amnii might save the child from severe pressure till it had reached such a position in the pelvis as to be easily extracted after the discharge of the waters. At fifteen minutes past five o'clock they

gave way during a pain, and a considerable quantity of liquor amnii was discharged. One of the feet came into the vagina; and, on carrying up my finger, I found the other foot and leg resting on the symphysis pubis. I brought it cautiously down, and, after doing so, found that the breech was firmly wedged in the superior cavity of the pelvis, with the back directed towards the mother's abdomen. The child was lively, and moved the legs freely; but on trying to assist it down, I discovered that the funis had unfortunately got round the thigh, and passed between the legs up the back, so that the child might literally be said to be riding across it. I did all in my power to rectify this untoward event; but from the diminished capacity of the pelvis, it was impossible to carry the hand sufficiently high to enable me to do so. I had recourse to the only alternative, of supporting the child so as to save the cord as much as possible from pressure. Immediately after the evacuation of the amniotic fluid, the uterine contractions became weaker and less frequent, so that twenty-five minutes elapsed before the body passed through the upper cavity. I then got the thigh disentangled from the funis; but, I am sorry to say, by this time the umbilical pulsation had entirely ceased. As it could serve no purpose now to prolong the labour, and the pains being slack, I administered the remainder of the secale at fifteen minutes to six o'clock. In a few minutes its action commenced, and capital pains followed; but independently of this, and all the efforts I could use, the head was not expelled till twenty-five minutes past six o'clock P.M., being five days, twenty hours, and twenty-five minutes, from the first exhibition of the secale cornutum, the patient having swallowed no less than thirty-four drachms of the medicine.

May 6th.—Has had almost no after-pains, and slept several hours last night; lochial discharge free; feels no complaint.

9th, 2 P.M. — Milk has been plentifully secreted; is already up, and taking charge of her household affairs. Dismissed.

REMARKS.—This case is highly valuable in two points of view:—1st. In

addition to the two cases previously published in the *GAZETTE*, it affords a most satisfactory proof that the secale cornutum is of itself sufficient to accomplish the induction of premature labour. 2d. It proves that a very large quantity may be given without producing the slightest bad effect or inconvenience, either to the mother or child.

That it is, to the exclusion of every other means, perfectly capable to induce premature labour in the advanced stages of utero-gestation, will, I think, now be admitted by every unprejudiced experienced obstetrician. If this deduction cannot be made from the three cases now before the profession, I do not know from what principle of logic the fact can be established. The details have been given at considerable length; indeed, the *minutiae* of all the different stages have been entered on with a fulness, and, I trust, fidelity, that, if they are carefully examined, no one, I think, can fail to arrive at a firm conviction of the truth of the conclusion I have drawn.

But it may be argued that the case, may prove a dangerous precedent for young or rash practitioners in tedious cases of natural parturition. Of this I shall speak hereafter. In the meantime, however, I do admit, that after I had given two ounces and six drachms of the secale, without producing the desired effect, I anticipated nothing less than a total failure; but, prompted by the feelings of the patient, the co-operating opinion of my esteemed medical friend, and the successful result of the two previous cases, the practice was continued, and the favourable issue has satisfactorily borne it out. Here two questions very naturally occur. What could be the reason of such a large quantity of secale being required in the present instance, when six drachms formerly produced the same effect with the same patient in much less time? If it is at all a uterine specific, if I may be allowed the term, why is its action so various that, in the case of Harriet Sander, three drachms produced the effect in twenty-two hours; while in Mrs. B.'s it required upwards of a quarter of a pound, and a period fully six times longer? The same answer may be given in reference to these questions as has uniformly been offered when endeavouring to explain the specific action of any medicine. The *modus agendi* is

unknown. I consider it as one of the *arcana naturæ*, which yet remains to be determined by the discoveries of some fortunate physiologist. But its use in practice cannot be objected to for this reason, till it has been satisfactorily proved how that the tartarite of antimony will in one case act as an emetic, while in another it has been known totally to fail. That the secale cornutum I used on the present occasion was good, I have no doubt, for I administered the same in my other practice with its usual success.

Having long directed much of my attention to this subject, from the observations I have made, I would offer the following explanation:—In proportion as the period of natural parturition draws near, *ceteris paribus*, so will the action of the secale be manifested on the system. The induction of labour was completed at least three weeks earlier than in her former case, as was evident from the comparative size and appearances of the children. The doctrine here laid down, I think, must be readily conceded; for it is rational to believe that, as the full period of gestation draws near, the natural predisposition of the uterus to expel its contents will be greater; consequently, a medicine, now almost universally admitted to act in cases of weak labour pains, will, from sympathy, more easily accomplish the object for which it was given; and hence, I believe, the reason why, when exhibited in parturient cases, where the uterine action has become weak, the small dose of a scruple, or half a drachm, has frequently produced such astonishing effects. This is well illustrated in the history of the present case. For a considerable time the medicine seemed to produce no effect, but the result has proved that this invisible action, or call it what you will, must must have been gradually exciting the uterine system to assume its expulsive functions, in the same way as we observe it done by the slight spurious pains at the commencement of a natural labour. As we trace the progress of the case, we find manifest improvement. Slight pains occasionally occur; the os uteri softens and dilates; and, finally, when a tendency to labour is fairly established, we have regular expulsive pains excited by the last two drachms, and these continue till the delivery is accomplished. It is true, I almost

despaired of success, but it was more from the want of experience in giving, or a precedent to give, so much medicine, than from a fear that the labour would not then be effected.

That inducing premature parturition is an unnatural process, no one can justly deny; and I believe that the earlier the period in which this is attempted, there will be the less likelihood of success—at least by the agent I have employed. It has been supposed that if the secale be found efficacious in strengthening the uterine contractions in natural parturition at the full period of gestation, it will likewise be effectual in the early months of pregnancy, and thus be had recourse to for the base purpose of procuring criminal abortion. Chapman*, Goupil†, Pellitier‡, and Planche, Gerardin§, Guibert, Lorinser, Waller, and several others, have entertained this opinion; while Steann||, Wesener¶, Villeneuve**, Chatard ††, Dr. Hall of St. Albans, one of the greatest declaimers against the use of the secale in any circumstances, Michell‡‡, and last, but not least, my respected teacher, Dr. Burns§§, with a host of other more modern writers, might be adduced, who deny its powers as an abortive. Several well authenticated circumstances have lately come under my notice, which, taken into consideration with numerous experiments made upon the lower animals, go far, in my opinion, to prove that this medicine can by no means be regarded as an abortive; though, from these circumstances and experiments, I am not as yet prepared to draw a line of demarcation as to the exact period when it may be said to act, as it were, specifically upon the gravid uterus.

The history of the present case shews that a vast quantity of the medicine may be taken with perfect impunity to the mother and her offspring. I have never, in the course of my reading, met with an instance where so much of the

medicine was given to an *enceinte* patient; but, from the moment she partook of it, to the period at which I write, she has not experienced the slightest unpleasant symptom, nor, indeed, have I ever observed any bad result from the use of the secale cornutum. Many experiments have been made by professional men upon themselves, with the view of ascertaining its deleterious effects; but as this medicine may be regarded as being chiefly applied to the uterus in its normal and abnormal states, and more particularly as the quantity employed in practice is generally small, I do not see what benefit can be expected to accrue to medical science from such experiments—especially as the experimenters are not endowed with a uterine system, upon which it is almost exclusively supposed to exert its action. Parmentier*, Goupil†, Michell‡, and Maier, reported by Wesener§, may be mentioned as those who carried these experiments to the greatest extent. Dr. Oliver Prescott|| has exhibited an ounce in a week in a case of amenorrhœa, and Michell¶ has mentioned that at Dr. Randall has given no less than six ounces in nine days, for the same complaint, without producing any prejudicial effect.

But it may be said that Mrs. B.'s case will afford a dangerous precedent for young practitioners in protracted labours at the full period of gestation. I wish it to be distinctly understood, that I deprecate the indiscriminate use of this medicine; I hold it as an invaluable boon to the obstetrical department of the profession, but its employment requires the utmost caution and discrimination. No one is warranted to give it without fully understanding the whole mechanism of parturition, and the general principles of labour; and even then its administration can only be admissible after the progress of the labour, with the presentation of the child, have been ascertained to be favourable.

With regard to the quantity to be given, I have tried it in all proportions, from a scruple to a drachm, but seldom have I found it necessary to exceed this

in any case where its use was indicated.

Much has been said by various authors respecting its effect upon the fœtus; and some have even gone so far as directly to accuse it of killing the child, as it were mechanically, in consequence of the violent uterine contractions which it artificially excites. It has likewise been supposed that its action has caused fatal asphyxia, by obliterating the circulation between the placenta and the infant. In the present condition of medical science these statements may well be regarded as mere gratuitous assumptions, and far from being proved. In short, the reason why the child's death is so often attributed to its action is, that it is only administered—at least should only be administered—in long lingering cases, in which, it must be admitted, that the offspring is frequently still-born where no secale has been exhibited. The case before us shows that no effect was produced upon the child, because, after the enormous quantity of four ounces had been taken, the movements of the fœtus were lively; and had it not been for the unfortunate circumstance of the funis being entangled with the thigh, and carried down before the body, I have not the slightest doubt that it would have been born alive. Several papers, for and against the use of the secale cornutum, have lately appeared in the GAZETTE and in the Lancet; but neither my time nor my space will at present allow me to allude to the doctrines they contain. I shall probably, however, on some future occasion, take the liberty of adverting to them; in the mean time, in concluding these observations, I cannot do better than quote the following very condensed analysis, from the valuable report of the Berlin Lying-in Hospital, by the celebrated Professor Busch. The original will be found by consulting *Neue Zeitschrift für Geburtshunde*, vol. xv. 1837:—In 175 cases, where it was given on account of weak labour-pains, after the os uteri was well dilated, 177 children were born: of these 142 were born alive, 18 in a state of asphyxia, but by proper treatment recovered; and 17 were born dead. On examining these, it was evident that 7 had been dead for some time previous to the administration of the medicine; and of the 10 others, which died during labour, 2 lost their

lives from prolapsus of the funis; 2 from turning; 1 from presentation of the nates; 1 from contracted pelvis and consequent impaction of the head; 2 from rigidity of the external parts; 1 from deformity of the extremities; and 1 from no very peculiar cause. Agreeably to this statement, therefore, only one death out of 177 births could properly be attributed to the employment of the secale cornutum.

This ought certainly to go far to silence the clamors of the *anti-ergotists*. That it may be capable of producing all the dangerous effects which they assign to it, I question not—but this is the *abuse*, and not the *use* of the medicine.

I am, sir,

Your obedient servant,

JAMES PATERSON, M.D., &c.

Stevenson Street, Calton, Glasgow,

SUGGESTIONS

ON THE

"PHYSIOLOGICAL PROBLEM" OF DR. GRIFFIN.

By DR. DAVID BADHAM.

(For the London Medical Gazette.)

I OBSERVE in some recent Nos. of the MEDICAL GAZETTE, that Dr. Griffin Limerick has, in a series of ingenious papers, invited attention to a topic, which, though more general in its bearings, is nevertheless very intimately connected with one which I had already briefly entered upon several years ago through the same channel, and subsequently, more at length, in Blackwood's Magazine. I had inquired into the grounds of the popular belief that insects design, intend, contrive, the works they execute; and partake of sensation in common with the higher order of animals. Dr. Griffin assumes, as beyond controversy, that insects feel; but would have us doubt with him, whether that which feels is necessarily and consequently conscious. Now that sentient beings are not therefore conscious, that is, in his sense of the word, self-conscious, is a proposition to which we should not demur; at the same time we cannot consider those experiments (performed or quoted) which he brings forwards as conclusive in proof of it: and as to ulterior conse-

quences, which your ingenious correspondent has drawn from such experiments, they appear to us to be liable to weighty objections.

In the papers above alluded to, I had endeavoured to make it probable, in opposition to popular belief, that insects are not endowed with sensibility: 1st, from certain essential anatomical deficiencies in their structure; 2dly, from certain invincible metaphysical difficulties arising out of the very nature and essence of individuality.

On dividing insects at their anterior and posterior corsets, and worms any where, as I had invariably found that the divided pieces of these creatures acted, so to speak, as when they were parts of a whole, in connexion with the rest of the body and the chain of ganglia entire, it was concluded that the office of these ganglia (the nearest approach to brain that such creatures exhibit), be it what it may, is one and the same office, and throughout their structure; and as all the ganglia cannot be brains, in the sense of ultimate recipients of sensation—points to which all impressions from without converge—none should seem to have more right to the attributes of brain than others. I had further argued that as sensation, motion, and nutrition, in the higher animals, may be properly considered to have separate orders of nerves; and as the first of these functions, sensation, is evidently an attribute of a higher order of being, or, it were better to say, a higher attribute than the other two, it would be no extravagant hypothesis (though in such subjects we would attach little importance to mere *à priori* speculations) that creatures might exist, to which sensation was neither necessary nor expedient; while to move and to be nourished, or to move for the purpose of acquiring nourishment, are conditions hypothetically inseparable from even the lowest grades of animal existence. But this is not all that can be urged in support of my heretical opinions: the amount of sensibility seems in all animals to bear reference to the amount of brain, or of functions accomplished by brain, or at any rate not accomplished where there is no brain (take intelligence, memory, and their consequences—docility and attachment), consequently it should be held, not only possible, but probable, that at a certain point in the scale of being (that point where those

intellectual qualities are either null or unobservable) sensibility will not be necessary.

The commonly and vaguely assumed proof of sensibility in the inferior tribes is the occurrence of certain motions, which, on the application of certain agents to their bodies, or the infliction of certain mechanical injuries on their structures, are taken for unequivocal indications or expressions of pain. No doubt motion comes of nerves. In whatever moves, a nervous structure, molecular, diffused, or associated, or in threads, is either to be seen or must be supposed: but to argue, from nerve being alike the organic agent of motion and of sensibility, that whatever moves also, and therefore feels, is to force the conclusion beyond legitimate warrant, and appears to me to be quite unauthorized. Motion and sensation have not the slightest analogy! they are such very different manifestations of nervous power, that, apart from the often demonstrably separate origin of the nerves, which in the higher animals subserve both, it is really strange how even a popular physiology should speak of the former as if it involved the latter, for no better reason than that contractions or changes in the disposition of moving fibres are observed in animals exposed to mechanical or chemical irritants which we know would inflict pain if applied to ourselves. It is surely conceivable, that the application of irritating agents may be felt, acknowledged, or responded to by motion, and not felt, acknowledged, or responded to by sensation; yet Dr Griffin, like many other writers, thinks it sufficient apparently to appeal to one result, when he would prove the other, since we find him speaking of the “sentient nature of certain movements,” and of the “sensation connected with, or necessarily dependent on, every nervous system.” These, however, and similar modes of expression, are far from peculiar to Dr. Griffin: throughout the Bridgewater Treatise of Dr. Roget, it is assumed that the final aim of all animal life is animal enjoyment, and that enjoyment is inferred from animal activity. Both these writers, however, had been long ago anticipated by Paley, who speaks confidently of the “joy” with which birds skim the water, with which fish spring in the stream, with which insects hop or fly, all which supposed evi-

dences of delight, however pleasing and familiar, and, we admit, in the more highly organized animals, unquestionably true, is, when applied to the inferior, no more than the argument from analogy, against which other analogies may easily be perceived: for what right have we to say, that the buzzing of a fly, or a bee, is so much enjoyment acquired by exercise of its wings. No one, says Dr. Griffin, will deny sensation and consciousness to a worm: nay, but the question is, on what grounds are sensation and consciousness conceded to a worm? is it that the ordinary movements of a worm appear to be voluntary; its seeming to choose or select means of escaping from danger? its hunger and thirst? its sexual propensities?—but are not the whole of these "facts" perhaps equivocal? Nay, in the experiments quoted, on undoubtedly sentient animals, which fly, walk, or hop, (according to their usual mode of progression) after decapitation, to say that they therefore feel, is to say that muscular movements can only arise from sensations; nor is it less an assumption to affirm that when paralysis results from division of the spinal cord, the animal which moves no longer, can therefore feel no longer. Mr. Carpenter, in his valuable paper on the voluntary and instinctive actions has indeed somewhat anticipated me in noticing that "those ideas about sensation, consciousness, and volition, which most persons mix up with their notions of instinctive movements, cannot be truly regarded as essential to, though they frequently attend them;" and M. Virey, in a recent meeting of the Academy of Medicine has, I observe, endeavoured to establish, that in the inferior creatures, the "nervous apparatus" is "chiefly for motion," and that it only becomes an "apparatus for sensation" as we ascend the scale of being.

The fact is, that all that relates to the physiology of the nervous system is so encumbered with bad metaphysics, as to vitiate many of its most important results; and it is to be regretted, that while the study of physics is risen into higher favour, and made compulsory, the study of mental phenomena is neglected, or its utility questioned.

This brings me to notice more particularly an argument made use of by Dr. Griffin, in his late paper, derived from the indivisibility of consciousness.

Sensation, he conceives to be "diffused and divisible;" while consciousness, as every body admits, is single, and incapable of resolution into parts. If for the words sensation and consciousness, which are abstract nouns, and cannot therefore, have any real existence, we substitute the phrases "a conscious being" and a "sentient being," we shall perhaps see our way more plainly, for self-conscious being is indivisible, granted; but why? merely because it is self-conscious? that assuredly is one reason; for where the perceiving and the thing perceived are one, (which is the meaning of self-consciousness) any violence offered to the oneness of either, destroys the whole conception; but, I repeat, is this the only reason why a self-conscious being is indivisible? Is it not evident that a being, *quâ* being, is indivisible, whether it reflect upon its own existence or not? Else, what do we mean by individual? But for the same reasons a being which feels, is, and can be, but one; to constitute the sentient equally with the conscious being, we are to suppose, as it were, one point in which the varieties of external impressions meet—one faculty by which, though unconsciously, the notices of these senses are classed under the category of pleasure or pain; while mere impressions on matter, though on the subtlest organ, have nothing to do with those categories. Our proposition is not that a worm, granting it to be capable of sensation as a whole, cannot be divided into several smaller worms, whereof each shall be endowed with a separate capacity of the same nature; but that, if that were the case, one individual would then have become many; or, that in dividing one body inhabited by one life, we have, as it were, created new bodies, each with its separate sensibility: which "creation" would not be at all more mysterious, by the way, than any other mode of generation; only it would violate the analogies of that process as usually observed in other instances. But, be this as it may, it is a very different thing to say, that one cannot be more than one, and to assert that there are no means by which one can become many. It is the former self-evident proposition which Dr. Griffin in fact contradicts, when he speaks of a "succession of momentary impressions" as constituting a purely sentient being; since it is plain that the permanent

identity of the percipient remaining the same, amidst the ever varying succession of the things perceived; (the oneness of the subject being undisturbed by the multiplicity of the objects,) must for ever lie at the very root of our conception of a percipient being.

REMEDIAL PROPERTIES OF SEA-AIR.

To the Editor of the Medical Gazette.

SIR,

To beguile the tedium of a sick couch, I have thrown together some observations on the nature and properties of sea-air, which, I trust, you will think of sufficient interest to merit a place in the *GAZETTE*.—I remain, sir,

Your obedient servant,

EDW. GREENHOW, M.D.

North Shields, May 23, 1839.

In a country like Great Britain, which, from its insular situation, possesses an extensive line of coast, it becomes a matter of some importance to ascertain what influence sea-air is capable of exercising over the functions of the human system, both that we may be enabled to judge how far a residence at the sea-side is conducive to health, and also in what cases it may be made available in the cure of disease.

From a very early period, sea-air has been held in great esteem for its bracing and invigorating properties, and there is no change so generally beneficial to invalids as a removal from a close and populous town to the sea-coast. This was well known to the ancients; and in the glorious days of Athens, the Archons were accustomed to resort to the Piræus to repair the ravages which luxury had occasioned; and at a later period, the patricians of Rome, during the heats of summer, were accustomed to leave the Eternal City and the Pontine Marshes, to breathe a purer air in their palaces at Baia; and at the present day, every one, from the noble to the mechanic, thinks it necessary to pay an annual visit to the coast: but while all are willing to admit the benefit derived from such a visit, few think of inquiring to what peculiar property of sea-air they are indebted for their increased elasticity of frame and exaltation of spirits. Some medical writers attribute

the effects of sea-air to its greater purity, being free from the taint of marsh effluvia; the soil on the sea-coast being for the most part dry, and also that the winds are unrestrained in their course by opposing objects—as trees; and thus admitting of a free and more uninterrupted circulation. Ingenious goes beyond this, and endeavours to prove that it contains a larger proportion of oxygen. In this, however, he has obviously failed, it appearing incredible that so subtle a fluid should exist in a greater abundance in one part of the atmosphere than in another; nor is such a belief in accordance with the known effects of sea-air upon consumptive persons. To what, then, are we to ascribe the peculiar virtues of sea-air, and in what respect does it differ from that of the interior of the country? In answer to these questions, I would say, its most important quality is its impregnation with saline and other particles, which it derives partly from the sea itself, and also in part from the different fuci growing on its shores. This impregnation probably consists principally of chlorine, but contains also a portion of iodine, which, being inhaled into the lungs, and also absorbed through the medium of the skin, imparts a more florid hue to the blood, increases the animal heat, and gives an additional impetus to all the functions of life. This, as I said before, is by far the most important property of sea-air, and one which exercises an extraordinary influence over certain diseases: those to which I more especially allude, are pulmonary phthisis and scrofulous affections, both of which are of much more rare occurrence at the sea-side than in the interior of the country; sea-air being evidently unfavourable to the development of these diseases.

I could point out more than three or four families which have each lost several of their members on attaining to a certain age, but have apparently arrested the invasion of the disease in other individuals of the family by making the sea-coast their permanent residence, and the remainder of the family have passed the critical age without falling victims to the dreaded malady. On the other hand, I know families, who, as long as they resided at the sea, evinced no tendency to pulmonary disease; but within two or three years after removing into the interior, first one member of the family

and then another have become the subjects of phthisis.

Such instances as these, together with the knowledge that phthisis occurs much less frequently on the sea-coast than elsewhere, can leave no doubt that sea-air is inimical to the formation of tubercles: how far it may have the power of retaining them in a dormant state, or of causing their absorption, I have no means of determining; but I have repeatedly seen patients who had been sent to the sea-side, whose delicate appearance was calculated to create uneasiness in the minds of anxious friends, particularly where one or more individuals of the family had died of consumption, whose little short cough, and hurried breathing upon ascending a slight eminence, together with the loss of flesh and strength, constituted a state which could not be viewed without apprehension, although no signs of organic disease could be detected. In these cases I have witnessed the happiest effects from a temporary sojourn at the sea; all these symptoms disappearing, and the patient regaining perfect health.

In cases of tuberculous phthisis, where the utmost that art can accomplish is to retard the progress of the disease and render the life of the patient more tolerable, the sea-coast offers peculiar advantages towards the attainment of these objects; the patient is perpetually inhaling the very substances which are the best calculated to allay irritation, and retard the progress of their disease; they are in the enjoyment of a more equal temperature, the ocean it is well known moderating the summer's heat, and mitigating the rigorous cold of winter; they are also in a great measure placed out of reach of the exhalations of living vegetation, which there can be no doubt exercise an influence over the organs of the human system: thus, hay-fever is said to be occasioned by the pollen of grass, which proves of so irritating a nature to the mucous membrane of the nostrils and air-passages of some individuals, as to produce the catarrhal affection so called; and this opinion as to its origin is corroborated by the fact that persons who are liable to it escape their annual attack by removing to the sea-side. If the pollen of the grass is capable of producing such consequences on some constitutions, is it not probable that similar causes, will operate in irritating the pul-

monary organs of consumptive persons which are already rendered morbidly sensible by disease? and it therefore becomes the duty of the physician to select such a spot for his patient as presents the greatest combination of advantages; and although the sea-side is the most eligible place in by far the greater number of cases, it is still necessary to exercise some discretion in selecting the place which is best calculated for each individual case; for while one patient is benefited by a mild, moist air, another requires a moderately cool and dry one. Were this more attended to generally, and change of air resorted to at an earlier period, there is every reason to believe that many valuable lives might be prolonged or altogether rescued from an early termination.

I may here mention that other organs besides the lungs appear to be affected by the exhalations of living vegetation. An intelligent farmer told me, that, whenever his home-field was sown with turnips, his family were sure to be affected with diarrhoea or dysentery in the autumn; and it is highly probable that our periodical returns of autumnal cholera may depend upon similar causes. This is a subject well worthy of investigation; and were we made acquainted with the disease prevalent in each particular district, and the nature of the cultivation, it would probably lead to very important results. What I have already stated respecting the effect of sea-air as being unfavourable to the development of pulmonary tubercles, is equally applicable to serofulous affections: they are of much rarer occurrence upon the sea-coast than elsewhere; and in the instance of strumous tumors we have ocular demonstration of the power of sea-air to cause their absorption. I have repeatedly witnessed its effect upon patients coming from the interior labouring under these tumors, which have gradually disappeared under the influence of sea-air without any remedial means whatever having been employed; at the same time I am not in the habit of relying on the effects of sea-air alone in these cases; but have for many years used sea-water, both externally and internally, the combined effect of which I have found so efficacious as to leave me no wish to employ any other remedy. My usual mode of proceeding is, to order either cold sea-bathing or warm sea-

water baths, according to the circumstances of the case; and, where the latter are used, the patient should remain an hour in the bath, if it does not produce exhaustion, and a sufficient quantity of sea-water should be taken every morning to act as a moderate purgative. When it is administered to children it is better to mix it with an equal portion of spring water, either warm or cold, according to the taste of the patient: this plan, together with a nutritious animal diet, and proper exercise in the open air, constitute a mode of treatment which I have found infinitely more successful than any other with which I am acquainted.

It would appear, then, that sea-air exerts a power inimical to the development of scrofulous and pulmonary diseases; and that in the former it will frequently effect a cure unaided by other means; and in the case of pulmonary phthisis, there is every reason to believe that it possesses a beneficial influence. Its mode of acting appears to be by imparting a more perfect vitalization to the blood, and giving a healthy stimulus to the glandular and lymphatic systems, and thus preventing those depositions peculiar to scrofulous tumors, and also of the formations of tubercles in the lungs, both of which I believe to originate in the impaired vital functions of these organs. Having mentioned those diseases of which sea air has the most obvious control, it only remains to notice in a general manner what diseases are the most generally met with on the sea-coast, and from what diseases it enjoys a comparative exemption; amongst the latter may be enumerated fever, both continued and intermittent, the one being extremely rare, and the other almost unknown, except when imported from Holland, or some other place. With regard to the exanthemata, I believe there exists no material difference between the sea-coast and the interior of the country; but I should say that inflammatory complaints, more especially croup and bronchitis, are more frequent at the sea side; and I think the same may be said of hemorrhages, both of which circumstances tend to strengthen the opinion that pulmonary phthisis originates in impaired vital energy of these organs, and not from an inflammatory or hemorrhagic tendency. Chronic rheumatism may also be in-

cluded amongst the complaints more commonly met with at the sea.

In conclusion, I may observe that it is a popular belief that sea-air is more salubrious than that of the interior, and that it possesses the property of conducing to longevity. In the present state of our statistical knowledge it would be difficult to adduce any facts in support of this belief; but my own observations would lead me to believe that our marine towns and villages do present an unusual number of aged persons; and also that the population generally enjoy more robust health than the inhabitants of the interior.

REMARKS UPON CLUB-FOOT, AND ITS CURE.

BY DR. GUSTAVUS KRAUSS.

(Read before the London Medical Society, on the
1st of April, 1839.)

[*For the Medical Gazette.*]

At the meeting of the 24th of September the question was raised, if it was possible to cure T. Williamson, a lad of about 18, affected with congenital varus of the worst kind. While I had offered to operate for this congenital distortion, Dr. Little thought it more prudent not to attempt a cure, on account of the high degree of the deformity, and the bony excrescences of the tarsal bones.

I beg to present this paper to the Society, not only to lay down the reasons that induced me to offer to operate on this patient, but also to give, in general, some of my views on this subject.

The anatomy of club-foot is intimately connected with its cure. As the extent of this paper does not allow me to enter into the particulars, I will remark but briefly, that I consider the displacement of the astragalus as one of the general and characteristic symptoms of varus, the ascertainment of which, whether it be primary or secondary, is highly important for the cure of varus, as it makes the condition of the two principal actions of the mechanical instrument, and as it is principally the deviation of the astragalus which often renders the cure of varus difficult, as the mechanical power cannot directly act against that bone. It deserves notice, that the superior articulating surface of the astragalus, on account

of its deviation, frequently becomes changed into two surfaces, running together in an obtuse angle, corresponding to the juncture of the articulating surfaces of the tibia and fibula, into which juncture the astragalus gets like a wedge.

Through the rotation of the astragalus there is formed a new articulating surface of the tibia, which is more hollow, and is situated more outwards and forwards. This circumstance is of great influence in the cure of varus, as in consequence of it, even when the foot is brought round as much as possible to its natural shape, the longitudinal median line of the foot, though it is parallel with the longitudinal median line of leg—that is, though continued over the dorsum of the foot—still lies more or less outwards than the latter; as I have observed particularly in cases of congenital varus, which I have cured in more advanced age.

If we consider that the astragalus frequently describes in the rotation round the longitudinal axis of the foot about a quarter of a circle (as its round head, in the natural position, placed on the inside of the foot, becomes situated outwards in a line drawn through the external malleolus, parallel with the ground and the outside of the leg); and if we further consider that the astragalus undergoes, besides, a rotation round its transverse axis, and is considerably changed in shape in consequence of its displacement; I ask, if we can then agree with Scarpa, that the displacement of the astragalus, if it exists, is but small in comparison with the displacement of the other bones of the tarsus and metatarsus?

The cause of club-foot is not yet quite so plain, and confined within such distinct limits, as Dr. Little asserts; and though I believe that most cases of club-foot originate through muscular contraction, I still think that the question is not yet so matured that we can deny the possibility of mechanical influence acting in the uterus on the limbs of the fœtus. I, at least, do not consider the question, whether club-foot in the uterus originates only through muscular contraction or not, as quite determined.

Dr. Stromeyer has the merit of having brought into general application the division of the tendons, as a wonderful means of curing certain deformities. The hundreds who are already indebted

to this simple operation for the recovery of the natural shape and use of their limbs, would still have dragged on their life as cripples but for his efforts. But it does not follow that Stromeyer's methods and principles are too perfect to admit amendment: on the contrary, I believe (and I have the intimate conviction founded on experience) that even after the publication of his book, there remained much to be done in the vast field of operative orthopædy.

Dividing tendons, notwithstanding it is a simple operation, is to be performed according to distinct rules.

The shape of the tendons, as well as their relation to the parts in the vicinity, are not always the same. This alters the conditions which are to be fulfilled in order to perform the division of the tendons in the simplest and safest manner; and it is therefore evident that it is not indifferent whether we use a concave or a convex knife, as Dr. Little does.

Stromeyer sets out from the principle, that division of the tendons is more easily and quickly performed with a greater part of the cutting edge of the knife than with its point: he therefore makes two punctures of the skin—one for introducing the knife, and another opposite where the point of the knife comes out, and uses a long fistula knife (sometimes a convex and sometimes a concave one), but without giving any rules for using the one or the other.

Though I think that it is not of much consequence to make two incisions or punctures instead of one only, I still consider Stromeyer's method of dividing tendons as by far not generally applicable. The following is to be observed in regard of dividing tendons with two punctures of the skin, and in regard of the choice of a concave or convex fistula knife:—

1st. The common fistula knife can only be used with advantage if the tendon to be divided is prominent, and if the part to which it belongs is of small volume, as it is the case with the tendo Achillis; because, if the handle of the knife cannot be depressed, its point would penetrate too deep, the skin covering the tendon would be injured, and the division would be difficult, if not altogether impossible.

2d. If the tendon is prominent, but the skin covering it is thin and tight, division with a convex fistula knife is

not to be recommended, by reason of the danger of injuring the skin covering the tendon.

3d. The division with a concave fistula knife can be practicable under the conditions mentioned above, as preventing the use of a convex fistula knife.

However, it is also desirable, for the use of a concave fistula knife, that the skin covering the tendon be not too tight.

4th. If a tendon is not prominent, and if it is not of a round but more of a flat and irregular shape, it is difficult, in using the concave fistula knife, to go at once round the whole of the tendon, as, at the same time, care must be taken not to penetrate too deep with the knife into the part.

If, therefore, a tendon is not prominent, though easy to be felt, and if its inner side (*i. e.* the surface directed towards the internal parts) is more flat, a convex *tenotome*, with a straight back, is preferable, if other circumstances allow it.

This particularly is applicable for dividing the tendo Achillis, if it is not prominent, as sometimes happens in grown persons, and frequently in children. Under those circumstances, it is required to press down the skin on the tendons inside with the back of the knife, in order to introduce the knife deep enough to pass through the whole of the tendon. A fistula knife would not be convenient for this purpose, and the division with a common convex *tenotome*, like the one used by Duval, is easily accomplished.

5th. Dr. Stromeyer's fistula knife has the disadvantage that its blade is too long, which renders its guidance more difficult and less safe, and makes the knife, by its thinness, liable to breaking.

Dr. Little does not quite follow Stromeyer's method of operating, as he generally avoids making a second puncture of the skin, using for the division of the tendo Achillis sometimes a concave and sometimes a convex knife. A concave knife is, however, improper for dividing the tendo Achillis, particularly if one does not choose Stromeyer's method of making two punctures of the skin, for the following reasons:—

1st. The front surface of the tendo Achillis is flat, and its back surface convex; the shape of the knife has to correspond with the shape of the tendon:

this is only the case with a convex, but not with a concave knife.

2d. In dividing the tendo Achillis, even with a convex knife, the part of the tendon that corresponds to its greatest convexity becomes divided the last, as attentive observations have shewn me. In dividing the tendo Achillis, I have often felt the cutting part of the knife distinctly as lying immediately under the skin on the tendon's outside and inside, and was astonished at the division not being accomplished, till I recognized the obstacle—namely, the thin, small, undivided portion of the tendon, corresponding to its greatest convexity; and I soon finished the division by sawing movements towards the above-mentioned convexity.

It is evident how much more difficult a concave knife will render the division of the tendo Achillis in this respect.

Dr. Little introduces the blade of the knife flat, and then rotating it through the quarter of a circle, directs its cutting edge towards the tendon, in order to divide it by sawing movements.

The performance of the operation in this way is less difficult, as one is more certain that the knife will not leave a portion of the tendon undivided, even if one has less practice in this operation. But the wound is not a simple puncture and incision, as the parts get more injured through the turning of the blade of the knife round its longitudinal axis, which is of so much importance as to induce me to reject this method of operating.

For dividing a tendon, as well as for the performance of other operations, the position of the patient is important.

The parts to be operated on should be kept quiet, and in a position in which the operator can examine with ease, and can follow the movements of the knife.

It is evidently inconvenient to place the patient in a chair for dividing the tendo Achillis, after Stromeyer's example, which is recommended by Dr. Little, as it is against one of the first conditions to be fulfilled, namely, to bring the back surface of the leg in front of the operator.

After the operation, the surgeon must examine accurately if every thing, of which division is required, is divided; for which purpose the sitting position of the patient is by no means proper. This may be proved by the 4th of Dr. Little's

contracted feet cases (Lancet, May 20th, 1838) in which, on the eighteenth day after the first division of the tendo Achillis, and after fruitless attempts made till this time to extend the foot, it was required to divide a band, which remained undivided in the first operation; and also by the 5th case (Lancet, June 22d), in which Dr. Little, on the second day after the first operation, divided a small string, which he left undivided on examining the limb. Supplementary operations of this kind may prove dangerous.

Through immediate and accurate examination after the operation, I have found that the characteristic noise, heard in dividing the tendo Achillis, is not a proof that the whole of the tendon is divided—in contradiction to Dr. Little's assertion, "*tum certo totus tendo conscissus est.*"

Though the division of the tendons produces in general but little reaction on the general system, it is still prudent to keep the patient on an antiphlogistic regimen and diet for about two days, especially nervous patients, in whom muscular spasms, caused by the operation, might favour inflammation of the wound. Under these circumstances I not only remove the patient from the excitement of light and society, but I also think that it is more prudent not to allow either meat or fermented drinks.

The mechanical part of the treatment of club-foot is by far the most difficult. It is especially required to have convenient apparatus to be applied after the operation.

Dr. Little has presented to this society the Stromeyrian instruments, which he has adopted—Stromeyer's foot-board, and Scarpa's modified shoe, which latter is used by Stromeyer for assisting the first attempts to walk.

I must remark that it is unnecessary to have two different instruments for the cure of club-foot, as a convenient one must serve for making the first attempts to walk as well as Scarpa's shoe, which cannot be used long for this purpose, and is soon to be replaced by a common boot.

Stromeyer's apparatus, though it acts in most of the necessary directions, has the following faults:—

1st. Simple actions are performed by a too complicated mechanism.

2d. The mode of bringing the instrument into action is deficient.

3d. A convenient construction for fastening the foot on the foot-board is wanting.

4th. The instrument is not convenient for straightening the curve, which the foot forms in varus.

5th. It acts not through an elastic, but only through a fixed pressure.

6th. It allows neither walking or standing.

I use for the cure of club-foot the instrument of my own, which has not been made without much trouble and repeated changes; and though it may appear rather complicated on the first appearance, I trust that in its effects it is the most simple that has yet been invented.

If I understood Dr. Little rightly, he now but seldom uses Stromeyer's apparatus, applying from the beginning Scarpa's shoe, asserting that it is sufficient in seven out of eight cases of club-feet.

According to my experience and intimate conviction, I consider that Scarpa's shoe is altogether improper, even as a mechanism, for the lateral inclination of the foot is wanting.

Dr. Little says, in his dissertation, "*De talipede varo**," that the weakened limb is to be sustained for some time in an instrument similar to that constructed by Scarpa, lest the patient should hurt the part by being too eager to walk.

On this I must remark, that in the treatment of varus it is but a secondary point to have an instrument in order to prevent injury of the foot; but the principal object is, to provide the patient with a shoe that renders walking possible. Scarpa's instrument is not fit for this purpose, for the reasons mentioned.

Besides a great desire to walk, even to such a degree that injury of the foot may be apprehended, is sometimes to be observed in individuals cured of pes equinus, but seldom or never in individuals cured of varus.

Dr. Little praises the advantage of air-cushions for the cure of club-foot; and I can also bear testimony to their usefulness, as even in 1836 I brought into practice the idea of applying air-cushions in order to moderate the pressure of mechanical apparatus, in the

* "*Debile membrum in aliquod tempus apta machina ad instar Scarpausae constructa sustinetur, ne segrotus nimia eundi cupiditate captus pedem lædat.*"

Orthopædic Institution of the celebrated Heine, at Schereningen.

Returning to the question, how far the higher degrees of varus admit of cure, I must first mention the difference that exists between congenital and non-congenital varus.

There can be no doubt that a deformity that is generally cured in a few weeks, must be materially different from another which is similar in appearance, but which generally requires as many months for its cure.

In non-congenital varus, displacement and change of shape of the bones of the foot do not arrive to such a high degree, the ligaments are looser, and the deformity is mostly maintained through the contraction of certain muscles; and hence follows the facility of curing non-congenital, and the difficulty of curing congenital varus. Dr. Little was therefore not correct in saying, "I therefore think that accidental varus does not differ much from connate varus*."

In that respect we ought to be more precise in naming the various kinds of club-foot, which is not observed by Stromeyer, as he relates under the head "Club-foot" very different cases of congenital varus. Varus, originating after birth, often forms a transition from pes equinus to varus, and is then to be called pes equinus varus, pied equin varus (Held. Duval).

The cure of non-congenital varus is, in general, possible up to the age which permits the division of the tendons; while not only the age and constitution of the patient, but also the degree of displacement and change of shape of the tarsal bones, and the degree of rigidity of the ligaments, make the conditions of curing congenital varus.

Dr. Little lays great importance on bony vegetations, regarding them as often preventing the cure of club-foot. Yet those bony vegetations are very seldom a hindrance, if we except that the articulating surfaces, which, through the displacement of the bones, do not enjoy their natural functions, partly lose their polish, and become rougher.

This, however, does not prevent the cure of varus, and we must remember the "*vis medicatrix nature*," which so powerfully assists the orthopædist in polishing the rough articulating surfaces, as it allows under other circum-

stances the formation of new articulations.

I do not believe that every congenital varus is to be cured, and do not think, with Dr. Little, that continued mechanical application would at last overcome every deformity of the foot; only in general, I say, that cases of congenital varus are very seldom to be met with which are incurable up to the age of 30, if the constitution of the patient is in favour of the treatment, and if he assist it with determination and patience.

I have had opportunities of examining in Germany, France, and England, a number of cases of club-foot; I must, however, confess that I have met with no case of congenital club-foot up to the age of 30 of which I would not have attempted the cure under the last-mentioned circumstances.

Though I remain within the limits of moderation as regards the highly important question of the possibility of curing aggravated cases of varus, a great difference will be observed in comparing my statement with Stromeyer's observations and cures, as the cases of congenital club-foot cured by Stromeyer, and related in his recent publication, are mostly relative to children of one, two, and five years old, containing but one case of congenital varus in a child of nine years of age, whose deformity was certainly but of a slight degree, as it walked with Scarpa's shoe in 28 days after the division of the tendo Achillis.

Without misapprehending for a single moment the merits of a man to whom we are so highly indebted, I must say, in the interest of science, that the means to cure aggravated cases of congenital varus consist in a suitable mechanical treatment, and that I would not undertake to perform the cure of an aggravated case of congenital varus with Stromeyer's instrument.

Dr. Little presented to this society, at the meeting of the 24th of September, a case of congenital varus club-foot, which was, as he repeatedly stated, the most difficult he ever cured. It was a young man about 20 years old, affected with a club-foot on one side only. In eight or nine weeks after the tendo Achillis had been divided, the foot had nearly resumed its natural shape, as is shewn by the plaster cast taken at that time, and presented by Dr. Little to the society.

* "*Ego igitur censeo, varum acquisitum, haud ita a vero varo differre.*"

Ulcerations taking place in consequence of the pressure of the instrument, afterwards retarded the completion of the cure for five months.

It is evident that a case of congenital varus that is brought nearly to its natural shape in eight or nine weeks after the division of the tendo Achillis, even by a rather imperfect mechanical treatment (Dr. Little did not then make use of the air-cushions), is not one of the worst kind.

In order to prove by facts the preceding remarks, allow me to present to the society several aggravated cases of congenital varus, in which a cure has been effected.

I.—John Stirling, ætatis 23, affected with congenital club-foot. January 3d, 1838, division of both the tendons of Achilles. More than three months were required to restore the deformed feet so far that they formed a right angle with the leg, and the foot being flat on the ground, the leg stood perpendicular on the latter. A plaster cast of the left foot, taken at the end of July, shews the shape of this foot at that time, when Stirling was able to walk two miles a day. He now walks five or six miles a day without inconvenience. Comparing his feet now with the plaster cast from the end of July, we find that the shape of the feet has been scarcely improved since that time, owing to the neglect of the mechanical treatment from the time Stirling commenced working as a shoemaker.

II.—John Burns, aged 28 years, affected with congenital club-foot (varus) of a very high degree. March 3d, 1838, division of both the tendons of Achilles. The division of the plantar fascia took place subsequently. On account of the rigidity of the ligaments, the patient's advanced age, and his poverty, the cure made but slow progress, especially as he was compelled to get his living by working during the time of the treatment. However, after overcoming the greatest difficulties, the deformity is now (a year after beginning the treatment) so far relieved as to enable Burns to stand on the soles of his feet, and to begin walking.

III.—G. B., 15 years of age, affected with congenital varus of both feet. The deformity was distinguished by an extraordinary rigidity of the ligaments. In the middle of September 1838 the mechanical treatment was begun. Oc-

tober 17th, division of both tendons of Achilles. January 4th, 1839, division of the tendons of both the tibiales antici muscles. The cure is now (*i. e.* six months after beginning the treatment) so far accomplished as to allow the patient to stand flat on the soles of his feet, and to begin to walk.

As I did not encounter great difficulty in exhibiting some of my patients, I beg to present three other cases of club-foot, cured by dividing the tendo Achillis, though they do not immediately illustrate the object of my paper.

I.—Maria, aged 12 years (daughter of Mr. Stakable, porter at the Parliament house), affected with pes equinus since her third year, arising without any evident cause. Division of the tendo Achillis, May 20, 1838. In a fortnight afterwards the foot was brought up towards the leg to an angle of about 75°. The patient now walks several miles a day without the least inconvenience or pain.

II.—George Bockock, 18 years of age, affected since his third year with pes equinus of the highest degree, in consequence of abscesses in the calf of the leg. December 4th, 1837, division of the tendo Achillis. He now walks from 15 to 18 miles a day on the sole of his foot without pain.

III.—Woodthorpe, inhabitant of St. Sepulchre's workhouse, 38 years of age, affected since his fifth year with hemiplegia, connected with contractions of the muscles of the calf, which produced pes equinus. May 9th, division of the tendo Achillis. He now walks 5 or 6 miles a day on the sole of his foot without any sensation of pain, while, previous to the operation, he could scarcely walk half a mile without great trouble and pain.

From the aggravated cases of congenital varus which I have presented to the society, we can best conclude whether the deformity of Williamson is to be cured or not, as this case is analogous to the cases related.

F. Williamson, the lad in question, about 18 years of age, was born with varus of both feet. Though of slender stature, he is of healthy constitution. Displacement and change of shape of the tarsal bones have reached in Williamson the highest degree. The rigidity of the ligaments is considerable, and will render the cure very difficult. However, attentive examination of the

deformity has shewn me that there is some movement in the ankle-joint, and that there can be no more question of bony vegetations than in the generality of cases of congenital varus.

The case of Williamson is similar to the case of Burns—i. e. the displacement of the bones of the tarsus has not reached a higher degree in the case of Williamson, but the ligaments are perhaps more rigid in the latter case, (similar to the case of G. B.)

The preceding remarks are, I think, sufficient to justify me, and to prove that I was supported by experience when I offered to operate for the cure of one of the highest degrees of congenital varus.

The question, I think, is important: it does not regard individual opinions; it regards principles which run through the whole doctrine of club-foot, from its anatomy to its cure.

These considerations may lead us further: they may shew how much public protection and benevolence is wanting for the numerous unfortunate beings labouring under deformities. General hospitals are not proper for their treatment, as not only appears from the nature of the object, but as experience has proved; the truth of this statement cannot but be recognized by the liberal feelings of the profession.

MEDICAL GAZETTE.

Saturday, June 1, 1839.

“*Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.*”

CICERO.

MEDICAL SERVANTS.

WHEN Sir Robert Walpole had retired from public life, he desired his son, Horace, to read him any thing but history, “for that,” he said, “I know to be false.” He probably preferred those masterpieces which, though nominally works of fiction, were really full of truth very thinly disguised. In like manner we have sometimes imagined that a reader tired of the inflated speeches, absurd scandal, and sham

news, which constitute a great part of ordinary journals, might turn with relief to the advertisements, in order to discover “the very age and body of the time, its form and pressure.” It is true that he would find bold fictions enough in the chequered columns of his choice; but they would be less apt to deceive him than the sugared fallacies of Lord John This, or Sir Harry That. After deducting, too, the rhetorical and poetical flourishes of certain announcements, much solid instruction would remain, the text for long and deep meditation; and the skilful critic might ascertain the domestic history of the nation in the registers of its wants and wishes.

In the earlier stages of civilization, mental culture is rare, and the few who possess it are eagerly sought for; their value being, of course, in proportion to their scarcity. This is the golden age, in the most literal sense of the word, for the members of the learned professions. They have to encounter great difficulties in attaining their station, but when attained it is respected*. At present the station is easily got, and little thought of. The difference is like that between ascending Mont Blanc and Primrose Hill. In this age of rapid changes, a few years make a striking alteration; and we have no doubt that a comparison between the journals of 1820 and the present time, would demonstrate how much more common the higher grades of education have become, by shewing how vast has been the increase in the number of lawyers, doctors, clergymen, tutors, and governesses, who offer their services to the public, and by the offer shew their superabundance.

* The benefit of clergy, or exemption from the penalty of death, for the first commission of some offences, granted to those who could read a verse of the Psalms in Latin, was doubtlessly founded in part on the unwillingness to lose a man of rare acquirements. A person was forgiven for not knowing the distinction between *meum* and *tuum*, if he knew how to decline them.

We have been led into this train of reflection by two singular advertisements which have appeared within a week, in which medical practitioners offer to go as servants. We copy one of them for the instruction of our readers, some of whom will, perhaps, be more surprised at it than we were :—

“To invalids and gentlemen.—Wanted, by a young man, a member of the medical profession, a situation to attend upon or travel with invalids or gentlemen. Would have no objection to perform the duties of valet. Can give the most satisfactory references as to character, ability,” &c.—Times, May 27, 1839.

Perhaps, indeed, those who have thoroughly digested our articles on medical competition, will rather be astonished that this method of escaping from the lower walks of our profession should only just have been hit upon. They will be inclined to illustrate it by that epigram in the Anthologia, where a professor of philosophy, raised by the Emperor Julian to the station of prefect, condoles with himself on his elevation. He laments the vulgar ambition which could induce him to prefer the silver chair of the governor to the ethereal seat of the philosopher, and cries out with curious antithesis, “Come! ascend downwards, for now you have descended upwards*.” The advertiser, on the contrary, if he should succeed, as we hope he may, in the object of his humble ambition, will ascend downwards, as the epigrammatist phrases it, and, like Antæus, will feel himself strongest when he has come down to the ground.

There is a story in the books, bearing the most evident marks of authenticity, of an Irishman, who, having come to London, was desirous of a ride in a sedan chair. His friends accordingly

gratified him by removing the top, seat, and bottom of the sedan, and pushing him along for the required distance; on which he observed, that if it was not for the name of the thing, one might as well walk. Now this anecdote, besides its literal meaning, clearly figures the state of those who, though nominally elevated above the commonalty, in reality are exposed to the same hardships, and “if it was not for the name of the thing, might just as well walk.” In fact, it is far better to walk, than to ride only in pretence, receiving infinite pushes all the while; and we have no doubt that the day on which the advertiser exchanges the solitary confinement of a medical assistant for the freedom of a valet, with kind looks and human sympathies around him, will be the happiest of his life. Still, this is not the kind of preferment usually held out as an encouragement to those who enter upon physic; and we therefore mention the fact as a warning to those parents who, with inadequate means, determine to thrust their sons into our profession.

LYING IN HOSPITALS.

In the progress of human institutions it seems often to happen, that after they have attained a certain degree of perfection, all further improvement is difficult or impossible; and unless their stationary condition is desirable, it becomes necessary to reconstruct them, using, of course, as many of the old materials as can be made available, just as people do when they pull down tottering houses. This rule applies to small things as to great, and it may be as necessary to discontinue a hospital as an Assembly or a Convocation.

Lying-in hospitals were first set on foot in this country less than a century ago. The advantages proposed were twofold; the first being that of offering an asylum to indigent

* Δευρ' αναβηθι κατα, νυν γαρ ανη κατεβης.

women in the hour of their greatest need ; the second, that of affording an excellent school for the instruction of practitioners. We believe, however, that it seldom happens that those in abject distress succeed in obtaining letters for lying-in hospitals, as this requires that the links which connect them with the upper classes of society should not have been utterly snapped asunder. Hence it commonly occurs that those who enter these establishments are pretty nearly of the same class as those who are treated at dispensaries. Now, in the obstetrical practice of dispensaries, the institution supplies a midwife and medicine ; a friend or relation is the nurse, or occasionally one is hired ; and, if necessary, some society sends linen for the mother and child ; and all goes on comfortably. If our facts, therefore, be correct, the majority of the hospital cases might easily be transferred to the care of the dispensaries, without loss to the patients.

But there is a class far below this, of women who seldom obtain admission to hospitals, but are delivered in parish workhouses, or perhaps in their own wretched abodes, under great disadvantages. For these it is most desirable that hospital relief be continued ; but the painful reply is, that the mortality is greater in lying-in hospitals than among the poor attended at their own homes. It might be urged, nevertheless, if the question were fully discussed, that though the deaths in the hospitals are more numerous than among an equal number of dispensary patients, they are possibly not greater than among those women who are *beneath* dispensary advice. But, in the first place, this is at least doubtful ; and even if true, it would be better to effect a greater diminution of mortality among the neglected class, by giving them

dispensary letters, than a smaller one by admitting them into a hospital ; supposing, of course, the dispensaries to be improved so as to supply these indigent women with all the comforts of which they stand in need.

Let us endeavour to investigate the question a little more fully by the help of the *méthode numérique*. If we take an extreme instance, we shall find that for many years the mortality in the Maternité at Paris was 1 in 25. This extraordinary destruction was not produced by famine, not want of medicine, nor too much of it, nor lack of good obstetrical aid. It seems to have arisen chiefly from crowding the women together, two or three having, at one time, been put into a bed. The puerperal atmosphere formed by assembling hundreds of women in one building may also have contributed to this result, as well as the patients not being selected from a tolerably comfortable class, as in England, but taken from among the most needy in the metropolis ; the hospital supplying in a great measure the place of the English workhouse. Whatever were the causes the mortality is frightful.

In British hospitals the mortality has been about 1 in 80 ; while in private and dispensary practice, it would appear from the tables in Dr. Merri-man's Synopsis to vary from 1 in 100 to 1 in 200. With regard to one of our institutions, the Westminster General Lying-in Hospital, Dr. Ferguson, in his late useful work*, accounts in part for its mortality from its situation. He says, " Its locality, rather below the level of the river, and surrounded by a mesh-work of open sewers fifteen hundred feet in extent, receiving the filth of Lambeth,

* Essays on the most important Diseases of Women. By Robert Ferguson, M.D. Part I, Puerperal Fever.

and some not thirty feet from the wards of the institution, may account for its unhealthiness."

Whether the hospital went to the sewers, or the sewers came to the hospital, does not appear, though we are almost inclined to suspect the former, as the hospital was rebuilt in a new spot not many years since.

But whether lying-in hospitals owe their superior mortality to a single disadvantage, or to a combination of several, the painful fact is but too certain. Our readers will recollect that, in an article on Public Hygiene, about two years ago, we came to the mortifying conclusion that lying-in hospitals do the reverse of saving life. The result, indeed, was clear enough on a bare inspection of Dr. Merriman's tables; but we believe that we were the first to give it so plainly in words. Dr. Ferguson will prove a strong ally in the cause of truth. In speaking of the fourth, or complicated form of puerperal fever, he says that when it is prevalent, the best thing that can be done is to shut up the hospitals; and adds his belief that the single chamber of the pauper is more wholesome than the spacious ward of the hospital patient. In another place he says of puerperal fever, that it is most fatal in hospitals, and that "neither the skill, the comfort, the careful dieting, and even the assiduous nursing, which are lavished on its inmates, diminish the mortality to a level with that attendant on the out-door population A lying-in hospital should consist either of a series of cottages, or its spacious wards should contain very few patients."

It appears from the first table at the end of the work, that the hospital was closed in February 1838, and again from April to November—the only efficient remedy for its ills.

The second object for which lying-in hospitals were founded—namely, that of

affording instruction—is, no doubt, worth attaining, when attainable without injury to their patients; but it would be a work of supererogation to prove formally that hospitals must not be kept up as schools, at the expense of patients' lives.

It must be confessed, that the difficulties which spring up even in the practice of benevolence are sometimes almost sufficient to give one pause, and make one exclaim with an elegant French writer*, "*Ah ! qu'il est difficile de faire le bien, il n'y a que le mal de facile à faire !*"

The remedies are obvious enough. A series of cottages might be built according to Dr. Ferguson's suggestions; or if this should seem too burdensome on a large scale, and even English philanthropy should at first succumb under the load, our dispensaries might be improved, so that the comforts now obtained at hospitals might be bestowed upon the patients visited at home. The scanty funds of these institutions are now, indeed, quite inadequate to this additional drain; but were it once known that such assistance is required, who can doubt that it would be freely given?

ROYAL COLLEGE OF SURGEONS IN LONDON.

STUDENTSHIPS IN ANATOMY.

Ordinance.

1. Two studentships in human and comparative anatomy shall be instituted, to be held by each student for the term of three years, at a salary of one hundred pounds per annum.

2. Candidates shall be members of the College, under 26 years of age.

3. The Council shall determine annually whether one or more of such appointments shall take place during the current year, and shall notify its resolution by public advertisement.

4. The appointment shall be made in the month of June, or as soon after as possible.

* St. Pierre.

5. The students shall be subject to such duties and restrictions as the Council shall from time to time direct; and in case of misconduct shall be liable to dismissal.

Regulations.

1. A Report shall be made to the Council, in the month of March, of the number of vacancies, or expected vacancies, in these studentships; whereupon the Council shall determine whether any, and what number, of such vacancies shall be filled up, and shall direct the necessary advertisements.

2. Candidates shall transmit to the secretary, on or before the 1st of May, their applications for the appointment, together with certificates of general good character and of fair acquirements in general learning, signed by two qualified members of the medical profession.

3. A meeting of the museum committee shall be held as soon after the 1st of May as conveniently may be, at which the applications of the persons offering themselves shall be examined, and, if approved, they shall be admitted as candidates.

4. The museum committee shall determine the mode of ascertaining the merits of the several candidates, and shall, after due investigation, report to the Council which of the candidates in their opinion possesses the highest merit.

5. Students shall attend in the museum daily (Sundays excepted) from ten till four o'clock, and shall be entirely under the direction of the conservators, who shall employ them as they shall see fit; and who shall have the power of granting leave of absence when they think proper.

6. In case of misconduct or neglect, the students shall be liable to be dismissed at any time by the president and vice-presidents, who are to report such dismissal, with the grounds thereof, to the next meeting of the Council.

EDMUND BELFOUR, Secretary.

May 10th, 1839.

. Upon the present occasion, the applications and certificates must be sent in by the 24th of June next.

ABERDEEN MEDICAL SCHOOL.

WE learn that in consequence of a misunderstanding between King's and Marischal Colleges, under whose joint superintendence the medical school of Aberdeen has hitherto been conducted, there will henceforth be two medical schools in that place; one under the patronage of each college. A question has been raised by King's College as to the right of Marischal College to grant medical degrees. Surely

this discussion might be satisfactorily terminated, if the latter body would publish the charter by virtue of which those degrees are conferred.

APOTHECARIES' HALL.

LIST OF GENTLEMEN WHO HAVE RECEIVED CERTIFICATES.

Thursday, May 23, 1839.

LECTURES
ON THE
CHEMICAL HISTORY, PATHOLOGY, AND
MEDICAL TREATMENT
OF
CALCULUS,
AND THE VARIOUS DISORDERS OF THE
URINARY SYSTEM.

By DR. VENABLES.

Stone in the bladder.—Calculi are found in the bladder more frequently than in any other situation. Nor is this surprising, because if we allow that the nuclei are formed elsewhere, in the kidneys, for instance, still they soon are sent into the bladder, where they increase by the gradual deposition of more calculous matter. But even the first deposit of calculous matter may take place in the bladder, and more especially if there should be accidentally any foreign substance introduced into the bladder, and which might serve as a nucleus for the first deposit. Here are a great variety of cystic calculi. In many of the instances of cystic calculi the bladder becomes thickened, and often the stones are contained in cysts; and sometimes they are so compressed by each other when there are several, that they assume various forms and figures, according to the nature and extent of the pressure. In plates 3 and 4 of Dr. Marcet's work, you observe very good delineations of the above facts. In the first, as you see, the cavity of the bladder is almost completely filled by a large calculus; and you may also observe that the coats of the bladder are very much thickened. In the 4th plate several calculi are represented lodged in distinct cysts, formed in the substance

of the bladder, between the fasciculi of the muscular coat, and pressing against others lodged in the contiguous rugæ.

Symptoms.—Stone, no doubt, must have prevailed from a very early period, and we find the symptoms of this disease described by the earliest writers of any authority. Thus we find Aretæus not only pointing out the various localities or situations of urinary calculi, but he even asserts what is allowed to be most probable in the present day, the renal origin of all urinary concretions, which all, he says, begin in the kidneys only, and pass as sand into the ureters, &c., and thus become the essence and sign of the disease*. Hippocrates also mentions calculi, and states that sandy urine indicates a stone either in the bladder or kidneys†. Celsus gives a tolerably accurate detail of the symptoms of stone. He states calculi may be known by the following symptoms:—The urine is voided with difficulty and slowly, sometimes by drops, and involuntarily, and is sandy; and in some cases blood, or something bloody, or pus, is voided with it. Sometimes a particular position, &c. is necessary in order to evacuate the bladder. Some, he says, void the urine more readily in the erect posture; some lying down on their backs; some inclined to one side, and ease the pain by stretching the yard. There is also a sense of weight in the part, which is aggravated by running, and every kind of exercise; and in many cases the pain is so great that the victims enfold

* Εγγίγνονται δὲ τοῖσι Νεφροῖσι μόνον, ἀλλὰ τοῖσι διαπύροισι. καὶ δὲ ἔδρην γὰρ ἐν τοῖσι Οὐρητήρσι οὐκ ἴσχονσι οἱ λίθοι, ἀλλὰ τὰ ψαμμία συν τοῖσι Οὐρητήρσι κάτω διαπλέει, τὰπερ καὶ σημήια καὶ ὕλη τοῦ πάθους γίγνεται.—*De Sig. et Caus. Diut. Morb.* lib. ii. cap. 3.

† Ὁκόσουσιν ἐν τῷ ὕρῳ ψαμμάδεα ὑφίσταται, τουτέοισι ἡ κυστὶς λιθιδῶ, ἢ νεφροί.—*Αph.* iv. 79.

their legs, changing and again refolding them, with the hope of obtaining ease*.

Gravel and gout are intimately associated; and Sydenham, who was a martyr to the latter, and also suffered much from the former affection, which, he says, is generally the exclusive companion of gout†, has given a very feeling description of calculus. He states, that in 1660 he was seized with a more violent and longer protracted paroxysm of gout than usual. After lying for two months, in the summer, upon a soft bed, towards the end of the fit he began to feel a dull and heavy pain in the left kidney, and occasionally but rarely in the right; and the pain in the kidneys remained even after the recovery from gout, which caused him to fear a stone, although the pain was not very acute, for he had not yet had a nephritic attack, which is attended with violent pain, stretching itself through the passage of the ureters towards the bladder, with violent vomiting. "In the winter of 1676," he continues, "presently after the breaking of a violent frost, when I had walked much and a long time, I immediately made water mixed with blood, and so I did as often as I walked much, or rode in a coach in paved streets, though the horses went gently; but this did not befal me how far soever I travelled in great roads that were not paved; the urine that I voided then, though terrible in appearance as passed, and almost like pure blood, in a short time the blood clotting and subsiding to the bottom, the urine assumed its own natural appearance.†"

We have already observed that calculi,

* Calculosi vero his indicia cognoscuntur: difficulter urina redditur, paulatimque, interdum etiam sine voluntate, distillat; eadem arena est; nonnunquam aut sanguis, aut cruentum, aut purulentum aliquid cum ea excrenitur, eamque quidam promptius recti quidam rescupinati, maximeque illi qui grandes calculos habent, quidam etiam inclinati reddunt, colemque extendendo, dolorem levant. Gravitatis quoque ejusdam in ea parte sensus est: atque ea cursu, omnique motu augetur. Quidam etiam, cum torquentur, pedes inter se, subinde mutatis vicibus implantant.—*Cels. De Medicin. lib. ii., cap. 7.*

† — "qui podagra fere individuis est comes."—*De Podagra, p. 584.*

‡ "Anno 1660, podagra me invasit, paroxysmo tum immuniore tum diuturniore, quam prius unquam. miserum affligens cum ex hac causa aestivo tempore, vel intra, vel supra lectum sub mollem jaceret ad duos menses decumbere, sub finem paroxysmi, dolorem hebetem et obtusum maxime in sinistro rene nonnunquam, licet rarius, et in dextro, cepi persentiscere. A podagra convalescenti hiebat utcumque renum dolor, qui per intervalla quædam, nullatenus acutus, sed satis tolerabilis, me submonebat; nondum enim paroxysmo nephritico (cujus sunt comites dolor ingens per ureterum ductus vesicæ versus tendens, tum vomitus enoribus), vel semel laboraveram. Quamvis vero nondum aderant ista calculi renum indicia, cum ratione tamen judicabam; me calculum, mole insigniorem in renum pelvi gestare; qui cum major esset, quam ut ex pelvi dicta in ureterum ductus

though perhaps originating in the kidneys, may leave their original position and occupy a different one: hence the symptoms will vary somewhat, according to the situation occupied by the calculus. Therefore we shall now proceed to consider the symptoms which indicate the formation and presence of stone in each particular situation.

Stone in the kidney.—Calculi may form in the kidney, and gradually increase, without even occasioning any very urgent or remarkable symptoms, by which we could be led to suspect the disease. If, however, it continue to increase, it may excite wasting, with inflammation and subsequent suppuration of the kidney, there is generally long protracted pain in the region of the kidney, attended with a discharge of purulent urine, and not unfrequently severe and copious hæmorrhage. Yet it is surprising that cases of this description may go on to a very great length without exhibiting any characteristic symptoms. The patient from whom the kidney delineated in this plate i. of Dr. Marcet's work was taken, "died of hydrothorax, without any symptom having occurred," says the Doctor, "which could lead me to suppose that there was any disease in the urinary organs."

The ancients were aware of the fact, that the symptoms varied with the situation of the calculus; and Aretæus details the specific symptoms attending stone in its different situations. He says, "if there be a large calculus in the kidney, the patient suffers pains in the loins, especially about the psoæ muscles, extending to the ribs; and this," he continues, "deceives many, who mistake it for pleurisy; a sense of weight in the hips; the back cannot be easily bent, and it is brought forwards not without trouble. There are torsions, with pain, and a sense of weight and twistings, because the organ is sinuous*."

elabi posset, prædicta symptomata non intulit. Quia in re post annos multos elapso me hallucinatum non fuisse certo comperi. Etenim cum bruma anni 1676 statim a soluto rigidissimo gelu diu multumque obambula-sem, urinae mox reddidi sanguine permixtam; idque toties mihi usu venit, quoties vel multum itineris pedibus confecerem, vel in curru per platearum pavimenta veherem, quantumlibet lento eorum gressu; quod mihi tamen non accidebat quoties per viam regiam, lapidibus non stratam, licet quam longissime, curru vectarer. Urina quam tunc exercebam, tametsi terribili sanguinis tantum non sinceræ specie prodiret, non ita diu post sanguine in fundo seorsim grumescente, in summitate limpida et sui similis conspicebatur."—Sydenham: *De Mictu Sanguineo a Calculo Renibus imparto*, pp. 693-700.

* Ην δὲ ἐμφραχθῇ κοτὲ τῇ κοιλίᾳ μέζων τελεθεῖς, πόνοι τῆς ὀσφύος ἀμφὶ τὰς ψῆας μεσφί των μεσῶν πλευρῶν. πολλοῖσι γούν ἀπάτη ποινῶς ἀπὸ πλευρίτιδος. βίρος ισχύου

It is generally, however, during the passage of a small renal calculus from the kidney along the ureter into the bladder, rather than during the formation of the calculus itself in the kidney, that the symptoms are most urgent. During the formation the pain is dull and obtuse in the lumbar region; but when the calculus is passing, the pain is intensely acute, shooting downwards along the course of the ureters. There is also retraction of the testicle, and sense of numbness of the thigh of the affected side.

The state of the urine will vary with the nature of the concretion or gravel; but it is mostly of a deep red colour. There is constant desire of passing the urine, while it is voided frequently, and only in very small quantity at a time; and it often deposits a copious brick-red sediment. Sometimes blood is discharged, or pus is found in the urine. Sometimes a thick, ropy, adhesive mucus is voided in very large quantity. In many cases the urine merely looks cloudy; but, after standing, a copious mucus subsides, and the urine becomes clear and transparent.

The stomach very frequently sympathizes, and then violent sickness and vomiting, thirst, flatulencies, eructations, and various other indications of disordered digestion? The constitution is also disturbed, and symptoms of fever, much resembling that which attends gout, appears. Aretæus says, with the dyspeptic symptoms, dry and acrid heats of the surface arise, with many of the other phenomena of fever; the tongue becomes dry; the bowels constipated; the frame emaciates, and loathing of food occurs; but if such patients should indulge and take any thing, it is digested with great difficulty*.

But although the above may be considered the usual symptoms of a calculus in the kidney, or passing from this organ through the ureter into the bladder, yet they are not to be regarded as absolutely diagnostic. If gravel or calculi have been passed either previously, simultaneously, or subsequently to the above symptoms, then there can be but little doubt as to the nature of the case. But it should not be forgotten, that symptoms almost identical with the above are sometimes occasioned

by various irritations of the urinary organs, as inflammation of the kidneys, of the mucous lining of the bladder, catarrhal discharges, and similar affections, without any urinary concretion whatever.

In the ureters.—The symptoms of stone lodged in these canals will be pretty nearly those already detailed above. Aretæus says, “that when a calculus passes into the ureter there is a shivering of the whole frame, as in shivering fits, and a feeling of the calculus passing with very violent pain*.” It is probably during the lodgment in the ureter that the vomiting, sickness, &c. are so severe and distressing, and that sympathetic fever runs so high. The urine is partially suppressed, or at least prevented, by mechanical obstruction, from reaching the bladder, and sometimes being re-absorbed into the circulation, produces a urinous odour from the patient, which is sometimes very sensible to the bystanders. At last the ureter either enlarges, and the pressure of the urine forces the calculus forward, and it then reaches the bladder, or the same may be effected by inflammation and suppuration; still it must be remembered that instances have occurred in which calculi were found in the ureters, and in which, during life, there were no distressing symptoms whatever.

In the bladder.—The calculus now passes into the bladder, and, if circumstances are favourable, it is discharged with the urine when passing in full stream. Under less favourable circumstances, however, the nucleus remains, and gradually enlarges by accretion from the deposition of new matter. The symptoms are often sufficiently distinct, and even characteristic. First, there is a sudden cessation of the pain in the groin and course of the ureters, which marked the progress of the stone through these canals. There is an uneasy sensation, often amounting to actual pain, felt at the extremity of the penis. This is perceived mostly upon the patient making some exertion, changing his position, or upon expelling the last drops of urine. Very frequently (and more especially in children) there is a sense of itching and an irresistible propensity to rubbing the extremity of the penis. The pain at length becomes more permanent, and much more intolerable, and there is a frequent and urgent desire to pass the urine. In many cases the urine is passed in mere drops; in others, a full stream is suddenly interrupted, and, notwithstanding the most urgent desire and the most powerful efforts of the patient, not a single drop

κατὰ ράχιν δυσκιμπτέες ξυννεῦσαι χαλεπῶς ἐπώδυνον στρόφοι, βαρέες ἀνέγκιστοι τὸ γὰρ ἐλικοειδὲς εντερὸν.—*De Sig. et Caus. Lit. Morb. lib. ii., cap. 3.*

* Ἦν καὶ πλημμυρῇ τὸ ὄδρον, καὶ διατάσιες, προθυμίᾳ ἀπουρησίως ὀκωσπερ ὠδίων φασάδες, ἀδιέξοδοι δε αἱ φασαὶ περιεὶ δακνώδες ἐπὶ ξηροῖ ἀναλὴ μὲν γλωσσο ξηρὴ δὲ ἡ κοιλίῃ. ἰσχυροὶ ἀπόσινται, ἣν δὲ τι προσάρονται οὕτε πέψαι, οὔτε ἀναλαβεῖν βῆθιοι.—*Ibid.*

* Ἦν δὲ εἰς τὸν Οὐρητήρα ὁ λίθος ἐμπέσῃ, βοασμὸς ὡς ἀπὸ ρίγους, αἰσθήσεις τοῦ λίθου ὑδοιπορέοντος ξυνὸν δροσισμῶ —*Ibid.*

can be passed till he changes his position, when the flow returns, and a considerable quantity of urine is voided. It is often observed that the pain and difficulty of passing the urine does not occur at the first flow, but after nearly all the urine has been voided, and but a few drops remain behind in the bladder, which now being no longer protected by the bulk of the interposed fluid, the stone now presses against some part of the mucous lining, more particularly about the neck of the bladder, which probably having its sensibility much increased, the pain is much more violent and acute.

When a calculus first arrives, a copious flow of urine succeeds; the fæces are discharged with frequent expulsions of flatus; quietude of stomach, belchings, the pains subside, and, the ureter being sometimes lacerated, blood is voided with the urine*. Mr. Wilson has given a most excellent description of the presence and subsequent enlargement of stone in the bladder:—"In the early stages of the affection," he says, "and when the stone is small, the patient, on changing his position or on making any bodily exertion, feels a peculiar sensation at the end of the penis, as if suddenly called on to evacuate the urine, although the bladder may have been emptied immediately before; this sensation occasions the sufferer often to apply his hand to the part where it is felt: in children, when affected with stone, such action is constantly occurring. The sensation gradually changes to absolute pain, becoming progressively more constant and more severe. The desire to pass urine becomes more and more frequent, and as the irritability of the bladder increases, so do the frequency and urgency of this desire; the urine, therefore, is discharged in very small quantities at a time, sometimes only drop by drop; occasionally a little blood accompanies the efforts to discharge it, and these efforts often bring on a painful tenesmus, and an irresistible desire to expel the contents of the rectum. In other instances the patient is for a time free from pain, and a tolerable large quantity of urine is allowed to collect in the cavity of the bladder, which, on evacuation, will flow at first in a full stream, and without pain, when suddenly the stream shall at once stop, although much urine remains in the bladder, and the desire of passing it still continues urgent; this desire is consequently increased by the stoppage, and becomes most distressingly painful; and in proportion to the efforts made to pass the urine by pressure, the difficulty is increased, and the pain aggravated. On

these occasions the change of position will do more than muscular efforts; for the stoppage being occasioned by the calculus gravitating to the orifice of the urethra, as the most depending part in the erect position; when the patient changes the position for the horizontal, and lies on his back, it then leaves the urethra open, by falling to the part now become most depending, viz. between the ureters. So long as the urine continues to flow in a copious stream, usually little or no pain is felt, the urine defending the neck of the bladder from the stone; but when only a few drops of urine remain, the conerected mass and irritable membrane then coming in contact, much pain is excited. The urine deposits a large proportion of mucous sediment, produced by the vessels and glands near the cervix of the bladder, being, by the presence of the calculus, excited to an increased secretion. Small portions of calculous matter occasionally come away with the urine, which on these occasions is generally, though not always, mixed with a ropy fluid, tinged with blood; but some calculi are so fine and hard that that this symptom does not take place.

"When the calculus obtains a large size, a dull but constant pain is felt at the neck of the bladder, and numbness and pain are sometimes perceived in the testicle and inner part of the thigh, extending downwards even to the bottom of the foot in some instances; a painful sensation of uneasiness is also felt in the back, which is increased by exercise, as, indeed, are all the symptoms for the most part; more especially by riding on horseback or in a carriage. The symptoms seem to be aggravated likewise when the stone presses upon the surface between the urethra and the ureters; and while in that situation, very violent fits of pain occur, which are only relieved by the removal of the stone to some other part*. Various positions of the body are tried by the patient to effect this removal; even those where the fundus of the bladder is made the most dependent part. In the case of the enormous calculus, which has been published by Sir James Earle, the patient, to evacuate his urine, was obliged to place his body nearly in a vertical position, and to repeat this sometimes every ten minutes†."

The pain and sudden interruption of the flow of the urine are regarded, by Sir

* If we suppose a line drawn from the entrance of one ureter to that of the other, and two more drawn, one from the entrance of each ureter to the neck of the bladder, the three lines will enclose a triangular space; every portion of which is extremely sensitive. It is here that the stone presses, on the evacuation of the bladder, and produces the most intense pain.

† Lectures on the Urinary Organs.

* Aret. de Sig. et Caus. Morb. Diut. Lib. ii. cap. 3.

James Earle, as diagnostic symptoms of stone in the bladder. But when calculi are lodged in folds of the mucous lining, they frequently occasion little or no inconvenience; or if they do, the symptoms are so obscure and equivocal that they will not enable us to distinguish them with certainty from those of several chronic diseases of the bladder.

The symptoms, as just now detailed, go on increasing, occasionally, however, remitting a little of their severity for a period of greater or less duration, when at length the patient's health begins to give way. Weakness, exhaustion upon the slightest exertion, listlessness, indisposition to activity, and incapability of either bodily or mental exertion gradually supervene; and whatever may have been the nature of the original diathesis, an alkaline state of the urine and a deposition of the phosphates succeed. The coats of the bladder become thickened, hardened, or otherwise organically diseased. Mucus or pus, or a mucopurulent matter, is thrown off in great abundance with the urine; the symptoms become more and more aggravated, till death at last puts a period to the patient's misery and sufferings.

In the urethra.—Calculi of small size are frequently voided with the urine, and consequently must, in such instances, necessarily pass through the urethra in their exit from the bladder. The urethra from the orifice to the bladder, does not diminish in size, but, on the contrary, rather dilates: hence bougies and catheters which can be introduced at the orifice readily pass into the bladder, unless they meet with some mechanical obstruction. But a body may enter the canal from the bladder, and be arrested in its progress from the diminished area of the passage. Many other causes also may tend to arrest the progress of a stone in this situation—for instance, stricture, inflammation and thickening of the mucous lining, small abscesses, &c. Yet calculi impacted in the urethra are not so frequent as might have been imagined. Its presence may readily be mistaken for stricture of the passage. Its effects, however, will soon unequivocally shew the nature of the case. There is always a partial, and sometimes even a total, suppression of urine; great pain in the particular spot in which the calculus is lodged. To this succeed inflammation, swelling, and thickening; and sometimes suppuration and ulceration.

Arætus mentions the retention of calculus in the urethra. "When the calculus passes into the yard," he says, "there is a new struggle; for if it be larger than the passage, it becomes fixed there for some time; the bladder is overfilled

and distended, and the urine is suppressed with very violent pain; for the ureters even with the bladder are filled and distended; but, being tortuous, they escape with difficulty*." He states further, that he has seen them hooked, and, as it were, some callous bits of flesh arise; but, for the most part, on account of the straight form of the canal, they assume an oblong form. They are of a white colour, argillaceous, which, he says, are generally found in children; others of a yellow and saffron colour, which occur more frequently in old men, in whom calculi in the kidneys are more frequent, but in children in the bladder†. It need scarcely be repeated, that a manual examination of the urethra externally, will greatly assist in determining the presence of a calculus impacted in the urethra. Plate 5, of Marcet's work offers a good delineation of a calculus in this situation.

In the prostate.—Calculi of the prostate may be recognized by certain symptoms which usually attend them when lodged in this situation. When the calculus has arrived at a certain size, there is usually some difficulty in passing the urine, with a sense of uneasiness and irritation about the neck of the bladder. But yet many cases have occurred in which even large collections of calculi have been found in the prostate after death, in which, during life, there existed no symptoms indicative of any such affection. Therefore a decisive diagnostic is wanting. In cases of prostatic calculi the prostate itself is generally diseased, and many practitioners regard the pain and uneasiness being increased by riding in a carriage upon a rough road, or upon horseback, diagnostic of a diseased gland. But these symptoms attend vesical calculi, and Sydenham's account of himself already quoted shews that they even attend renal calculi. Sir A. Cooper determined the question by manual examination. "A gentleman, about 21 years of age, became subject to a suppression of urine, for which Sir Astley was consulted. Upon passing a catheter,

* Αγωνίη δε δεύτερη, τοῦ λίθου ἢ δια τοῦ καυλοῦ διέξοδος. ἢ γὰρ μέζων τῆς Οὐρήθρης ἔη, ἐνίσχεται πολλὸν χρόνον, καὶ πλημμυρεῖ ἡ κύστις, καὶ ἰσχυροῦν νῦν ἐπαλγεστέρη· ξὺν γὰρ τῇδε καὶ Οὐρηθρὴς πλμπανται.—*Ibid*.

† Χαλεπωτάτῃ δὲ ἡ τῶν σκολιῶν διέξοδος· καὶ γὰρ καὶ ἀγκιστρειδεῶς ὥπως, καὶ ἐπὶ τοῖς πόροις επιπυρώσιαις. ἐπιμήκειες δὲ τὰ πολλὰ διαπλάσσωμενοι ὑπὸ τῆς τῶν πόρων ἴξιος· χροῖτῃ, δὲ ἄλλοι μὲν λευκοὶ ἀργιλώδεες, τὰ πολλὰ παιδίοισι· ἄλλοι δὲ ξανθοί, κροκοειδέες, γερουσι, δὲ οἱσι περ καὶ ἐν Νεφροῖσι οἱ λίθοι ζυνηθῆες· ἐν Κύστι γὰρ παιδίοισι μαλλον.—*Ibid*.

a grating sensation was felt at the neck of the bladder, and the finger being introduced into the rectum, some calculi could be felt moving in a cyst within the prostate, and a distinct clashing could be heard as their surfaces were pressed together. It was proposed that a small incision should be made through the rectum into the prostate, for the purpose of extracting the calculi; but the gentleman would not consent to the operation*." This gentleman having died a few years afterwards, on dissection the prostate was found to contain a large number of calculi, as was also the case with the kidneys. The ninth plate of Dr. Marcey's work, as you see here, illustrates the prostate gland diseased and full of calculi. Upwards of a hundred of these calculous concretions were found in the gland. If a calculus, or even a fragment, should happen to be passed, its chemical composition—phosphate of lime—being almost exclusively confined to prostatic calculi, will at once decide the nature of the case.

LECTURES ON THE

VENEREAL DISEASE,

*Delivered at the Aldersgate School of Medicine,
March 1839,*

By F. C. SKEY, F.R.S. &c.

LECTURE V.

ON THE PRIMARY INDURATED VENEREAL SORE, OR TRUE SYPHILITIC CHANCRE.

The true syphilitic sore—marked by great induration—attended with or without ulceration. —Sore affecting the glans.—Sore affecting the prepuce or body of penis.—Syphilitic lubo.—Sore throat.—Three forms of eruption. —Mottling. —Psoriasis. —Lepra. —Iritis.—Treatment of syphilis.—Action of mercury.—Mercurial treatment indispensable.

This form of sore presents, in all its stages, characters in direct contrast to the destructive form of disease, described in the two last lectures. The characteristic of phagedæna is ulceration; that of syphilitic disease, deposition. In phagedæna, the action is rapid and irregular; in syphilis, it is chronic and uniform: in fact, the general and local symptoms are so discordant in character, and so dissimilar in origin and progress, that it would appear almost impossible to confound them.

Syphilis, by which I mean the primary sore, commences at a more remote period from sexual intercourse than any other

form of venereal affection, seldom appearing within a week, averaging about ten or twelve days, and being occasionally detected at the remote interval of four or five weeks; and I beg your attention to this fact, as an important diagnostic mark of its peculiar character.

Its presence is first observed in the form, not of a sore, but of a "circumscribed thickening;" and to the description of this very rare form of disease, Mr. Hunter doubtless applied those terms which have become of late years so notorious, however inapplicable to it may be other parts of the same. The syphilitic induration may also follow a more or less extensive excoriation, most frequently attacking the corona glandis. What may be the mode of its first inoculation it is difficult to determine; possibly, by the abrasion of a minute portion of surface which afterwards heals, leaving for a time no trace of its existence. This circumscribed induration or cellular tubercle, gradually extends, and becomes excoriated on the surface, which is slightly elevated above the surrounding level. This surface may cicatrize and become again excoriated, the extent of the exposed surface holding relation to the increasing size of the mass below. Its colour is that of a deep or tawny red, varying in depth according to the more or less inactive nature of the disease. The surface, when irritable, is rough and flocculent, is not excoriated, never exhibits (in the language of Mr. Hunter) "a fair loss of substance," and secretes a fluid which is neither purulent nor puriform. It appears in the form of a red, raw patch, on an elevated base, having in its early stage no circle of inflammation around it, and being unattended with pain or much inconvenience.

Syphilis, like other venereal sores, exhibits degrees of torpor. The induration may continue to extend during two months, without excoriation of its surface, or the formation of any kind of sore. When it attacks the glans, it may occasionally extend through one-half or two-thirds of its substance, without materially altering its form, being still a "circumscribed thickening," and presenting to the eye little more than the appearance of a hard swelling of the part. This affected portion of the glans may be entirely abraded, exhibiting a raw red surface of superficial ulceration, uniform with the surrounding level; but it is always marked by great induration.

Should it extend towards the frænum, it will convert it into a hard, somewhat thickened, and solid cord. The frænum rarely or never breaks down under the early influence of syphilis, but assumes the character of hardness of the neighbouring disease; yet it almost invariably

* Marcey, &c. p. 19.

ulcerates under the curative action of mercury. I have examined such forms of affection, when situated on the glans, with a magnifying glass, and have not been able to detect the smallest breach of surface. When the prepuce is affected, the thickening is more distinct and circumscribed; and on denuding the glans, the diseased portion rolls over in a mass, from its inability to adapt itself to the more gradual eversion of its remaining part. This, however, is not characteristic of syphilis alone, but exists in any disease attended by partial effusion into the laminae of the prepuce, the product of simple irritation. Still, there is a wide difference between the appearance on retracting the prepuce in disease, the result of simple inflammation, and that of syphilitic induration. The former is not circumscribed, nor is it absolutely, but only relatively hard; while the latter is often truly distinguished by the term "cartilaginous hardness."

If it attack the glans at the orifice of the urethra, it will generally involve the whole circle in a callous ring, contracting the opening to an extent injurious to micturition. There may be no appearance of abrasion, nor even of increased vascularity, except within the orifice, from which an ichorous fluid exudes in small quantity.

The direct contrast to this more general form of the sore, when situated on the glans, is found in that on the body of the penis, which is more active and inflamed, larger on its surface, and more consistent with the description I have given of the sore in general. The excoriated or ulcerated surface is of a deeper red, secretes a larger quantity of sanious fluid, and is attended with more pain. It is sometimes in colour almost black, approaching in appearance to the character of slough; but even in this state it will remain for several days without undergoing any considerable change. If in this condition the sore be neglected, it advances by slow but positive ulceration, which encroaches on, but never destroys the thickening surrounding it; for the thickening invariably characterizes the disease through all its stages.

The deposition here is the disease, and the ulcerated surface is consequent only. You cannot form a favourable opinion from the aspect of the ulcer, of the condition of the disease itself, any more than you can determine favourably of an open cancer, because it throws out apparently healthy granulations, tending to cicatrize; nay, the granulations of cancer do occasionally skin over with a pellicle of cuticle, which delusive action has excited many a vain hope of improvement. But

here, unfortunately, the ulceration is not the disease, but, as I have stated in an earlier lecture, its effect only; the real disease remains unaffected. So in syphilis, the ulcerated surface may become clean and granulating, skin will form over it, and it may then return to its original state of simple deposition; but this change is temporary and delusive; the surface will again ulcerate, and the disease slowly extend, so long as the form of treatment which alone can reach it be withheld.

Bubo is an occasional, but not a general attendant on the syphilitic sore; and its characters are somewhat peculiar. It does not appear in the form of a general swelling, extending above Poupart's ligament like a mound, involving not only the glands but also the cellular membrane of the groin, but commences by a simple enlargement of one or more glands, the outline of which may be felt rolling under the finger. These glands enlarge but slowly, partaking of the chronic nature of the primary malady; they rarely advance to suppuration, nor, indeed (as has been observed by Mr. Welbank), is pus a common secretion in any form of syphilitic disease.

This form of bubo can hardly, I imagine, be referred to the product of simple irritation, unless we can suppose two kinds of irritation; because the more usual form of bubo—viz. that arising from gonorrhæa or from venerola—are the products of a disease that excites no specific constitutional affection, and must therefore be the effect of simple irritation; as the glands of the groin or axilla may be inflamed and enlarged, in injuries of the foot or hand. Now if the bubo of syphilis were the product of such irritation, we can see no reason why the same form of enlargement, and that of the same textures, should not prevail in each example: but it is otherwise. In the one case, the cellular membrane is so far involved as for the most part to conceal from the touch all outline of a glandular structure; in the other, the gland is for some time distinct, and independent of the cellular atmosphere (to use an old fashioned phrase) around it. Practically, this feature is not important; because, be it specific or not, it is so little prone to change, so rarely advancing to suppuration, that it can have no influence on the treatment to be employed.

Without treatment, the constitution imbibes the poison of the local disease; the manifestation of which may occur at an interval of from six weeks to three months from the unhealthy cicatrization of the primary sore, and is ushered in by accelerated pulse, general pains of a rheumatic character, head-ache, loss of appetite and rest, and followed by an affection of

the throat, and also of the skin, in the form of an eruption. Either may be first affected. These constitutional phenomena are, however, by no means invariably so distinctly marked as we observe them in phagedænic disease.

The throat is attacked by inflammation of a torpid character, affecting the tonsils and soft palate, preceded by dryness. One side only may be for a time affected, but more generally both. The colour is paler than in common sore throat, or in that of phagedænic disease, and more partial in its extent. The patient complains of little pain in swallowing, so long as the surface is not destroyed. The tonsils then ulcerate, and present a whitish cavity, which cannot be mistaken for a mere aphthous ulceration, being (as Mr. Hunter expresses it) a "fair loss of substance dug from the tonsil." I am not aware, however, that in this respect it differs materially from other forms of ulcer of the tonsils. The inflammation, which at first appears somewhat defined and patchy, and which I have seen occupying the two front arches of the palate for a period, without affecting the posterior, now becomes more extensive and diffused, and the difficulty of swallowing is increased, though apparently not in the ratio of the extending evil.

Now, gentlemen, let me recommend you never to profess the power to determine a venereal throat by examination by the eye alone. When you have acquired some insight into the subject by your own personal inquiry, I am satisfied that you will never commit yourselves to such an absurdity. Those who profess this knowledge, imagine that Mr. Hunter has clearly pointed out landmarks so precise and definite, that the commonest observation may readily detect them. I am not aware that any author since the publication of Mr. H.'s book has dilated on this subject, nor any who has professed knowledge so exclusive. But the professional public think they know a venereal throat, because they think Mr. H. knew it. In truth, Mr. Hunter made no such profession. He honestly states that *there are many forms of sore throat*, some of which are venereal, and some not; and he moreover says, "No man will be so rash as to pronounce what the disease is by the eye alone." And here Mr. H. was unfortunately mistaken, for many men are rash enough to commit this error; but then, observe, they are not men who have studied the venereal disease; if they had, they would be cautious in pronouncing judgment on a subject of so much difficulty. Mr. H. says, "the true venereal ulcer of the throat is, *perhaps*, the least liable to mistake (to be mistaken) of any of the forms of the disease." It is not, however, to ulcer of the throat that a hasty

and rash opinion is limited; but it *extends to that of mere inflammation, in which we have, in reality, still less to guide us*. Some forms of venereal sore throat are characteristic; and, as Mr. H. says, the true syphilitic (*i. e.* venereal) ulcer is least liable to be mistaken; as are the phagedænic ulcer of the back of the fauces, and the snail-track form of ulcer extending along the arches of the palate; but they are not necessarily venereal, and they can only be determined with certainty, by collateral inquiry.

The eruptive disease exhibits itself in one or more of three forms, of which the first and simplest is that which is called *motting*; but it is important to observe that, although a frequent attendant on it, it is not peculiar to syphilitic disease.

It consists in a patchy discoloration of the skin, varying in depth of colour, from the lightest pink to a distinct red, abrupt in its margin, and slightly rough to the touch. Like a large variety of cutaneous eruptions, it fades on the approach of cold, appearing more distinct on the application of any forms of stimuli that tend to promote the cutaneous circulation. It appears most generally on the chest, front of the arms, and on the groin; it may also appear on the face or forehead. The patches are often very large, giving an altered tint to the surface, of some inches square.

The two eruptions, however, that especially characterize syphilis are psoriasis and lepra.

Syphilitic psoriasis appears in the form of circular spots, about the size of a small finger-nail, generally round, or nearly so. These spots are based on disease, not of the cuticle, but of the skin, which is inflamed and thickened, giving to the spots a slight degree of elevation, perceptible to the touch, on passing the finger over them. The base is red, or of a reddish-brown, and from which the cuticle peels in dry scales or flakes, from the period of their first appearance; they are therefore characterized throughout by the scaly eruption. The process of desquamation occurs not in large, but often in minute and broken scales of morbid cuticle, and much less considerable than in some other forms of scaly disease; and this constitutes the prominent feature of the affection from the commencement, by which it is distinguished from the desquamation of pustular, vesicular, or papular eruptions, for in these the desquamation attends the latter stage only.

The syphilitic psoriasis often makes its first appearance on the scalp and forehead, on the chin or upper lip, and back of the neck, and more frequently extends to the chest, abdomen, front or inner surfaces of the arms, chiefly about the elbow-joints,

to the palms of the hands; also to the front and inner part of the thighs. Eruptions of all kinds are modified by the density of the surface they occupy; therefore we are not surprised to find syphilitic eruption of the palms somewhat peculiar. It forms what has been called a honeycomb eruption; the cuticle separates slowly in circular patches, and is imperfectly reproduced. Mr. Carmichael first remarked the also peculiar appearance of syphilitic eruption, when situated on commissures of skin, or where two cutaneous surfaces are in contact, as at the nates, or between the toes. Here there is no desquamation nor dryness, the eruption being more inflammatory and moist, like a soft and highly organized wart. I am inclined to think, however, that this appearance is not peculiar to syphilitic disease, as I have seen it in phagedæna, as well as in other eruptions, unequivocally not venereal. It is very rare that phagedænic eruption appears on the palms, but I have seen it distinctly marked in more than one instance.

The third form of eruption is that of lepra, which is obviously pathologically identical with the last-described eruption, but appears in larger and deeper patches, surrounded by a narrow inflammatory ring, and based rather on the subcutaneous tissue than on the skin. These eruptions form encrustations of a brown colour, raised considerably above the surface, which separate as the substratum ulcerates. The crusts might be mistaken for the rupia of phagedænic disease, but they are slower in forming, and may be determined by the character of the eruption around. The eruption of syphilis—be it psoriasis or lepra—is always characterized by desquamation of the morbid cuticle throughout its progress. The entire eruption appears dependent on one single cause, and that a general, and not merely a local one. If one part advances, the whole advances. We need not expose the entire person of a patient, with the view to ascertain the condition of the eruption on a remote part of the body, as is required in the case of phagedænic disease, in which we find the actions of health and of disease variously intermingled—some spots desquamating in the last stage, while new ulcers or rupial crusts are forming elsewhere; but, as in the exanthemata, the whole surface appears obedient to one common influence. Syphilis, unless in a very advanced form, rarely affects the whole surface; those parts I have already mentioned being most obnoxious to it; whereas phagedæna is less discriminate in the surfaces it involves. As a general rule, subject however to exceptions, the front surface is the seat of early syphilitic

eruption, the back in a greater degree that of phagedæna.

Syphilis is a slowly advancing disease, and never bursts out into violent and unforeseen destructive morbid actions; while phagedæna is constantly liable to these changes. Syphilis is rarely a destructive disease, while to phagedæna must be referred the extensive catalogue of injurious mutilations which are generally charged to venereal disease.

On this subject, however, I must refer you to an excellent paper, by Mr. Welbank, in the 13th vol. of the Med.-Chir. Transactions. To Mr. Welbank I owe great early interest and much valuable information on this subject, which I am anxious to avail myself of every opportunity to acknowledge. To its study he has successfully devoted a large portion of his professional life, and he has succeeded in accumulating a fund of important information on the pathology and treatment of venereal diseases, which I conceive to be not surpassed by any surgeon of our time.

Iritis is a rare attendant on syphilitic disease. When the iris is inflamed it is generally affected singly, and occurs at a later date than when attendant on phagedæna. It is supposed to be characterized by earlier deposit of lymph than any other form of this affection, and it warrants the fullest exhibition of mercury for its cure.

Affections of the bones, and of the larger joints, are among the more remote consequences of syphilis, all of which are marked by slower, but more regular action. Periosteal inflammation is, however, less frequent than in phagedæna, and there is little or no propensity to suppurating nodes. Pains are often referred to the substance, more especially of the long bones, and to different regions of the body, which do not appear referable to the bones.

The treatment of syphilis is essentially mercurial, although the possibility of subduing its influence by other means has been thoroughly established by the army surgeons. Mr. Rose, in a paper you will find in the 8th vol. of the Medico-Chirurgical Transactions, states that he had treated successfully all the venereal cases of the Coldstream Guards during a period of twenty-one months, without mercury. Mr. Guthrie, as the result of an extensive experience, says, "Every kind of ulcer of the genitals, of whatever form or appearance, is curable without mercury;" in which opinions Dr. Hennen and Mr. Carmichael fully concur. With such evidence before us, who can doubt the fact? The question, however, is not whether the *scaly disease* of Mr. Carmichael can be cured without mercury, although the establishment of that fact was of great value in subverting the universal faith in the indis-

pensability of mercury to the cure of any form of venereal disease; but the question is, whether its treatment without mercury is in all respects the best: and on this subject there can be little hesitation as to the course to be adopted and preferred. The influence of mercury on some constitutions is formidable, while in others it is harmless. We have recourse to its use internally with a view to effect one of three objects: 1st, that of a purgative; 2d, that of the so-called alterative; and 3d, with a view to produce in the system some remarkable effects, which are said to be due to the specific influence of the medicine, chiefly on the absorbent system; and the production of which is considered essential to the cure of certain forms of disease that experience has proved subject to its power. In respect of the first I have nothing to say; of the second and third, however, I am myself anxious to learn how far they may be deemed identical in action, however varying in degree.

The influence of the "alterative" appears to be directed to diseased actions chiefly; it is said to correct unhealthy secretions, to diminish unhealthy enlargements; in short, to use the language of my friend and colleague, Mr. Pereira, "it indirectly induces healthy action in a very slow, gradual, and incomprehensible manner." The third effect, or rather the third degree, is that of a sialogogue, for the effects of large and continued doses are numerous. When employed in such quantities it excites secretions of all kinds, and among the foremost that of the salivary glands of the mouth, attended, when persisted in, by swelling and ulceration of the gums, fetor of the breath, swelling of the tongue, and great prostration of strength. These are among the more striking effects of continued doses of mercury, or they may occur in peculiar idiosyncrasies on the administration of minute quantities.

This is the important agent, the influence of which has been long employed in the treatment of venereal sores, and of which the first observation I wish to make is, that you are not to consider it in the light of a direct antidote to the poison it is employed to supersede. Its influence is merely but strictly indirect, and is exerted by producing a condition of constitution unfavourable to the propagation of venereal disease. "I am," says Mr. Carmichael, "decidedly of opinion that mercury acts by exciting an irritation capable of superseding that of the syphilitic, and in this point of view it can be of little consequence by what quantity of mercury, whether little or great, that irritation has been excited. But whatever be the quantity, it is necessary, for the cure of syphilis, to excite a strong mercurial action, and to

make the constitution feel and suffer under the debilitating influence of the mineral."

When speaking on the subject of venereal disease, I told you that that disease did not require mercury in such doses as to produce ptyalism; that it might occasionally, in obstinate cases, be given in limited doses, such as 5 gr. of blue pill, every night. In phagedæna, I stated to you not only that mercury was not required in the early stages, but that the effects of mercury too closely resembled the disease it was employed to cure, to be otherwise than most objectionable; although it was occasionally used with advantage in the later stages.

In syphilitic disease it is our great resource, and the only remedy on which we rely with confidence. But with what effects—to what degree is it to be employed?—because, as I am indifferent to the injurious influence of the mineral, I am ever solicitous to attain the end in view with as small a quantity as is necessary. Mercury acts as a sialogogue—that is to say, an action by which is produced a large increase of saliva from the glands secreting it. But the presence of mercury in the system is rendered apparent, short of its influence on the salivary glands—viz. by the inflamed and puffy condition of the gums, and by the fetor in the breath. The question is, then, whether salivation (an effect often remote and obtained with difficulty) is essential to the cure, or whether the object cannot often, perhaps generally, be obtained by the minor quantity?—and here we may appeal to experience. Where mercury is employed in the last stage of phagedæna, it has always appeared to me that salivation was most undesirable, and that the influence of mercury on the gums and on the breath was all that was required. I believe the observation to be equally applicable to its administration in either primary or secondary syphilis. Not that I object to an increased secretion of the salivary glands in moderation; from which, however, in itself, no possible advantage can be derived, seeing that salivation is *not a very infrequent symptom of syphilis* before treatment; but I confess I cannot withhold my humble protest against that indiscriminate and universal resort to the baneful influence of mercury, which can find no advantage short of extremes.

I believe that the constitution will rally, and often in a short time, from the consequence of a severe course of mercury once employed, as we find in the parallel example of loss of blood; but that the effects of a second and third ptyalism are in a compound degree more injurious; till, however, at length, after repeated salivations, the constitution may become comparatively insensible to its influence; and it is in this latter condition of the constitution that it

may often be employed with advantage in phagedænic disease. But, on the other hand, I am not blind nor indifferent to its injurious effects on the future health of those on whom it has been lavished with an unsparing prodigality, for the cure of diseases which are trifling, in comparison with those it has engendered. How many examples of health and prospects blighted, through personal disfigurements and mutilations; severe and protracted suffering from rheumatism in every form; dropsy; latent pulmonary disease fanned into activity; phagedæna itself, with its horrid catalogue of ulcers and necroses—these and various other diseases, no less serious in degree or kind, may date their birth from the often useless and generally indiscreet use of this mineral poison! We have ample experience of the harmlessness of mercury when employed *largely* during a short period—a month or five weeks, for example, or even longer; but, as I have before stated, it is the repetition of its use—the renewal of its administration often before the health has completely rallied from the influence of the former salivation, and this followed by a third and a fourth appeal to the medicine, each more severe and debilitating than the former; then is it, with the physical and mental powers of the miserable subject gradually wasting, phagedænic ulcers of the throat and skin, incrustations of the nose, both within and without, suppurating nodes, hectic fever, and general emaciation, that a steady, continued, and effectual course of mercury is once more demanded, in the vain hope of subduing a poison that is fostered by its presence, and compared with which the most virulent and destructive pox I ever had the good or ill fortune to witness, is as a dwarf to a giant.

Mercury employed in phagedæna is often for a limited period beneficial, but rarely when pushed to the extent of ptyalism; and thus we are deluded by the specious influence of the mineral. In syphilis its advantages are perceived from the moment its influence is felt by the circulation. The improvement is steady and progressive; the symptoms recede, as Mr. Hunter announced to us, in the inverse order of their appearance: first the sore throat or eruption, and lastly the primary sore.

It is rare that syphilitic disease exhibits itself after a mercurial course. Where it does appear the mercurial action has been imperfect, and must be renewed. This is an unpardonable error in the surgeon; for the same ground, under increasing disadvantages, has to be retraced. It is objectionable, because mercury in a thoroughly unmercurialized constitution is a much more efficient antagonist to syphi-

litic disease than in a constitution once and recently the subject of its influence. In the second instance larger doses and longer time are required, although salivation is more readily attained,—a proof, if any were required, that mercury is no antidote to syphilis, but merely that the irritation or disorder it creates is incompatible with the presence of syphilitic poison.

Mercury may be employed either internally or by inunction. It is generally preferable to combine them, giving each in a mitigated quantity. For ordinary cases, five grains of blue pill night and morning, combined with the fourth or sixth of a grain of opium, added to the inunction of a drachm of mercurial ointment every night on the thighs, or in the axillæ, will produce swelling of the gums and soreness of the mouth in the course of from four to six days. Often larger doses are required: calomel may be substituted for blue pill, in doses of two grains, with half a grain of opium to prevent its action on the bowels, every six hours. Some practitioners prefer the compound calomel pill; but it is of little moment how the effect is produced, provided it be obtained. When the gums are thoroughly inflamed and sore, to the extent of compelling the patient to eschew solid food, the mercurial action must be maintained continuously; this does not require persistence in large doses. The maintenance of the effect may be accomplished by their reduction to about two-thirds of the former dose; and this should be unremittently continued, not only until the secondary eruption and primary sore have entirely cicatrized, but until the indurated base of the primary sore is wholly absorbed; for in this base slumber the elements of disease, which will burst forth with renewed energy at no remote period, should the patient lack perseverance in the necessary treatment. The diet should be reduced, and the patient confined to a uniformly warm temperature. It is not desirable, however, to reduce his strength by depletion, although moderate depletion may accelerate the appearance of the mercurial action. As soon as this object is attained, you may order sarsaparilla, the tonic influence of which will not interfere by diminishing the mercurial action, while it will uphold the strength, and shorten the period of after-recovery. It is not necessary to persist throughout the entire treatment in the reduced scale of diet, particularly if the presence of a mere induration, following the healing of the sore, demands the persevering use of the mercury, when all the other forms of the disease have subsided.

When all local and general appearances have disappeared, all that remains

for us is to endeavour to replace the patient in the position he occupied previous to his illness; and this may be effected by good diet, moderate use of wine, or the compound tincture of bark, and change to a purer atmosphere.

OBSERVATIONS
ON
COMPLICATED SURGICAL
INJURIES,

INCLUDING GUN-SHOT AND OTHER WOUNDS.

By RUTHERFORD ALCOCK, K.T.S. &c.

Late Deputy Inspector-General of Hospitals with
the Auxiliary Forces in Portugal and Spain.

(As delivered in his Lectures at Sydenham
College School of Medicine.)

[Continued from p. 332.]

**I.—INJURIES OF THE HEAD CONSIDERED
FIRST MERELY IN RELATION TO INJURIES
OF SCALP AND FRACTURES OF BONE.**

Peculiarities of fracture in bones of the head, and their classification in reference to diagnosis and treatment.—Simple fractures, with and without depression—direct and by countershock.—Compound fractures, with and without depression—with loss of substance—with and without lesion of dura mater—with lodgment of foreign body.—Scalp wounds.—Principles of treatment.—Puffy scalp simulating fracture.—Burrowing of matter.—Erysipelas.—Treatment by free incisions.—Opposite tendency of the instructions of many writers.—Cases in illustration.—Depression.—Principles of treatment.—When to interfere by operation.—Modes of operating indicated by different kinds and degrees.—General conclusions.

In the lectures devoted to fractures, I told you that there were some bones the injuries of which should rather be considered with reference to the vital organs within, than any violence done to the osseous structure. Such are the bones of the head, of the spine, pelvis, and thorax. In these the fracture is only of secondary importance, while the injury inflicted on the brain, spinal column, thoracic and pelvic viscera, command the most urgent attention, since the consequences frequently involve the life of the patient.

Before I proceed to consider these graver injuries of the head, it may be as well to indicate the various forms, the nature, and the treatment generally,

of scalp wounds and fractures of the bones of the head, unattended or uncomplicated by any other injury. Such cases occasionally occur; and this seems the simplest manner of bringing before you a class of injuries at once the most important and complicated. Physiologically and pathologically viewed, they are also the most interesting in the whole range of surgical science.

The skull, from its position, is more exposed than other bones to accidents and injuries. It is not only liable to fracture by direct violence applied to the part, as when a man falls upon his head, but the vibration and concussion communicated through the spinal column will produce its worst form of fracture, as by a fall from a great height upon the feet, or perpendicularly on the sacrum, giving rise to a fracture of the base of the cranium.

Another peculiarity not met with in other bones, or only in lesser degree, consists in the fracture often taking place in an opposite direction to the part which receives the blow. This is in accordance with a law of physics, by which an arch, if overloaded, gives way at its weakest part. The most frequent seats of immediate injury are the forehead, occiput, or centre of parietal bones. If the blow does not fall with such force as to crush in all before it, the frontal, parietal, or occipital bones may escape fracture where they are struck, the arch giving way where it is weakest—that is, across the base.

Fractures of the head you will find divided, in many surgical works, into two chief classes—those attended with depression, and those without: a classification faulty in two ways; for simple fractures here, as elsewhere, should for practical purposes even be distinguished from compound; and there is another class not included—that is, where portions of skull are entirely removed, as by sabre cuts. I have seen in the same head the skull divided for several inches across the head, in cuts extending from the forehead to the occiput, and two large elliptical portions taken out: it was the case of a Miguelite officer, who died about the eighth day, in a field hospital under my charge. Here concussion is less, probably, than where fracture takes place from ordinary causes, but the danger of inflammation to the membranes and brain very much increased. This patient died from

inflammation, lying for several days in a state of great excitement and delirium, which continued to the last. On the eighth day, as I stood by his side, he started up from a partially supervening stupor, which was palsying alike his eye and tongue, and with kindling animation gave the word of command to his troop—"Forward, and on to Cartaxo!" Poor fellow! he had indeed reached Cartaxo—but without his troop: he fell back as he spoke, and the next moment was dead. Cartaxo was our headquarters, and had been the object of the battle in which he fell, while charging with his squadron. I regret I have not his skull to shew you, for a head so carved and hewn I have seen but once. The living, however, at this period left me no moment to bestow upon the dead.

Class these fractures of the head, as those of all other bones, into simple and compound; and each of these into cases with depression and without. To the compound add two subdivisions—1. with loss of bony substance; 2. with presence of foreign body.

Although it is quite true that the bad symptoms accompanying a broken skull do not arise by the mere breach of continuity in the bone, which, on the contrary, is of comparatively trifling importance, but from these injuries being united to others, such as concussion, lesion, inflammation of brain or membranes, &c.—for I need hardly remind you of the difficulty of breaking a man's skull without shaking its contents—yet still, if the patient be not destroyed by these, then the differences in the original nature of the injury lead to practical distinctions in the treatment, and differences in the results.

When there is not depression or lodgement of a foreign body, the fracture has nothing to do with the symptoms, which may exist with or without fracture, and only indicate injury to the nervous matter. The sickness, giddiness, loss of motion, &c. have no relation to the fracture, unless by the circumstances of pressure from bone or other substance introduced through the fissure. These are effects referrible only to concussion, &c. The mere fracture of the bone has not more influence than a fracture of the humerus.

Apart, therefore, from the symptoms and effects to be referred to concussion or pressure from various causes, and inflam-

mation, fractures of the bones of the skull offer but few points of interest, and still fewer indications for peculiar treatment.

As we are considering the injuries of the head for the present merely in relation to contusions or wounds of scalp, and fractures of bone—viewed as contusions, wounds, or fractures simply, I shall content myself with a very few observations on their various degrees, their nature, and treatment.

And first of scalp wounds.—There is no principle of greater importance than that which is now well established—thanks, in no small degree, to the exertions of Mr. Pott—viz. always to replace any torn or displaced scalp, and endeavour to produce union. I cannot but think, in many points connected with these injuries, that he laboured under considerable error; but even so, it is in a great measure redeemed by this practice, to the establishment of which he so much contributed. The removal of a portion of scalp will generally lead to detachment of the pericranium by sloughing. You will remember that I told you, in my lecture on the bones, that any injury to the investing membrane was very likely to lead to exfoliation, and all the worst diseases of the osseous tissue. That as the short and flat bones were nearly entirely dependent upon these membranes for their nutrition and vitality, injuries to these were still more carefully to be guarded against or treated. The long bones are plentifully supplied by a nutritious artery, of which the bones of the skull are deprived. Hence the frequency of exfoliation from injuries of the scalp and head. You also saw how injury to the periosteum by a sympathetic action caused disease of the medullary membrane, and sometimes in the worst forms. Apply this knowledge to the bones of the skull, and you will see that injury to the pericranium is likely, in a similar manner, to affect the dura mater, which is not only the investing membrane of the skull, but also of the brain; any diseased action, then, in this, sinks into insignificance as regards its effects, even on the bone, for it implicates the centre of nervous power, and gives rise to inflammation of the most fatal character, involving the brain.

Hence it follows that all scalp injuries must be treated with careful

reference to the pericranium, and that the principles of treatment already laid down in previous lectures for injured periosteum, and parts covering, apply here, only more rigidly, and in a more important degree. If there be detachment of the scalp, with or without abrasion of the pericranium, immediately and carefully cleanse and replace the parts; endeavour by every means to procure adhesion, and restrain the inflammatory action within these bounds. The following case, which came under my care many years ago, will prove how much may be effected by this careful treatment:—

James P—, fell from a first-floor window and pitched upon his head, laying bare nearly the whole of the left half of the frontal bone, making a large triangular flap, bruised and covered with mud, hanging over that side of the face. His neck, right arm, and ankle, were also injured. I saw him a few minutes after the accident; the parts were carefully cleansed, the flap laid down, and the edges kept in apposition by a suture at the apex of the triangle. He had neither fever nor headache; the parts united nearly entirely by the first intention. He was kept in a darkened room perfectly quiet, starved, freely purged, and a cold lotion applied. In ten days he was quite well, with the exception of some swelling about the ankle.

It has been said by Mr. Abernethy that the dura mater detaches in the same proportion as the pericranium. This is not, however, exactly as I have observed it. Here are many very fine specimens. In no case does the detachment of the dura mater and pericranium exactly correspond. Generally, as you may observe, the dura mater is more extensively detached. This is a preparation of great interest; the pericranium in this case was extensively detached; but the dura mater, although diseased, was so far from being detached, that it was unusually and strongly adherent. The principle, however, established by Mr. Abernethy, I hold to be a true one, taken with some little modification. Injury to the pericranium leads to corresponding disease in the dura mater.

Simple fracture, with contusion of soft parts.—Extravasation of blood beneath the scalp, great effusion of lymph, swelling, discolouration, heat, redness,

pain and tension, with more or less of general disturbance, are the usual attendant symptoms on these injuries. The first step, then, is to clear the head of hair entirely, by which you bring under observation the whole of the scalp, relieve the head of a warm covering, and facilitate the application of all remedies. This was a general order enforced in all the hospitals under my direction, the moment patients were admitted, and I have had ample opportunities of appreciating its good effects.

Secondly,—Ascertain if there be displacement or depression. In making this examination, let me recall to your mind an observation already made, that a violent blow on the scalp always produces an exceedingly hard circumscribed swelling, round its edges particularly, by the effusion from the capillaries, while the part which received the blow is flat, the cellular structure condensed; thus there is circular hardness with a depression in the centre. You must feel this yourselves, before you can be aware how identical is the impression communicated by these effects, with actual depression of bone. And you must have examined many heads with and without compression before you will acquire the power of readily and surely discriminating. The importance of correct diagnosis is great; for although you are in no degree authorized in performing an operation if other symptoms of pressure do not exist, yet as these may be present independent of fracture, they do not of themselves give satisfactory indication; and even if pressure did not arise from several causes, we have not yet attained the degree of knowledge necessary to distinguish in all cases between concussion and pressure. The slight variation in the feeling communicated, no directions will suffice to enable you to distinguish. Take every opportunity of examining most carefully injuries of the head, and you will, by experience and attention, easily acquire the power.

If it be decided that there is not depression, apply a cold lotion over the whole surface of the head; purge freely. If you cannot effect the cleansing of the alimentary canal by medicines given by the mouth, use injections with castor oil, and, if necessary, croton oil; but take care the bowels are emptied. A blow on the head very generally acts as

an excellent emetic, and secures the unloading of the stomach. After this, if the patient can swallow, give antimonials and salines; act generally upon the secretions; keep your patient perfectly quiet, without food, and in a darkened room, for light is a powerful stimulus to the brain. If the concussion or extravasation be not to a fatal extent, the patient will gradually recover; the injury to the scalp and the bone beneath will also be repaired by healthy inflammation. The absorption of all effused matter removes the swelling, calculated at first to mislead, in a few days. This treatment, as far as it goes, is equally applicable to the most severe forms of injury.

Sometimes, however, violent inflammation of the scalp sets in; matter forms under the occipito-frontalis muscle and fascia, or between the pericranium and skull; there is great tension, redness, and heat; the suppurative action is running on to the gangrenous; often complicated with erysipelas. Your patient now is becoming each hour in a more dangerous and less satisfactory state; and if active and judicious measures are not promptly taken, delirium and death will result. If the state of pulse sanctions depletion, bleed freely; and let me observe, that in severe injuries of the head, there is in particular stages a very slow pulse. I have had several such cases lying side by side in the same ward, with pulses varying from 38 to 60, and that for many days together. On this symptom and its causes I shall enter fully hereafter. I refer to it now, to tell you that you must judge of the state of plethora not by the *number of pulsations*, but by their *character*. If you find the pulse either hard, wiry, or of full volume, but laboured, you may bleed with advantage, even if the pulse be 40; and, indeed, you will observe disease is as much indicated by an unnatural slowness of pulse as by rapidity. On these distinctions there is much important information to be conveyed. If the pulse permits, then, bleed freely; I do not tell you until 20, 24, or 30 ounces have been abstracted; for, as I warned you, bleeding should always be regulated by *effects*; bleed, then, until you have produced an effect on the pulse—until it becomes less hard, wiry, or laboured, and somewhat more accelerated in its course. Leeches to the neighbourhood of the injury are doubtful remedies where there is any

disposition to erysipelas, and not to be recommended. Blood abstracted from the temporal artery would be better, and this may be so performed as to produce the effect either of local or general bleeding.

If there be any indications of suppurative or gangrenous action, ushered in with heat, tension of scalp, &c., relief is only likely to be afforded promptly and efficiently by two or three *free* incisions down to the pericranium, or if matter has formed between this and the bone, then down to the skull. And these may often require to be three or four inches in extent. Let them bleed freely if you have any indications of plethora. It is easy to secure the arterial branches when you wish to stop all further hemorrhage, even if the small vessels do not retract and close spontaneously.

I am the more anxious to impress this practice upon you, from a tendency in the writings of some of our best surgeons to condemn it, or rather in their anxiety to counteract that reckless meddling with these injuries, and cutting down upon fractures, without any defined or sufficient motive, formerly much in vogue, and perhaps occasionally adventured on even now by those who have no fixed principles of treatment, and think they should do something, without knowing what—to control these meddlers, they have almost erred on the other side. Under the treatment I have here recommended, your patients will often do well, when by temporizing or less active measures, they would sink and die. One of the most remarkable instances I remember, and which first impressed upon me the value of this treatment, occurred in a patient of Mr. Guthrie's, admitted in the Westminster Hospital during the period I was house-surgeon, ten years ago. A man had fallen from a building of great height, broken half the bones in his body, and covered it with contusions.

His head had suffered severely by blows; erysipelatous inflammation rapidly set in on the scalp, with great heat, tension of parts, and delirium. Mr. Guthrie, whom I sent for, made four free incisions down to the bone in some places—in various directions, where the tension and diseased action seemed the greatest. Several twigs of arteries were allowed for some minutes to bleed freely; the delirium rapidly subsided; the scalp took on a healthy

suppurative action; and he recovered without any ensuing bad symptoms.

Another not less remarkable instance of the importance of relieving the tension and inflammation under these circumstances occurred some time back. Col. T., who received a fatal gun-shot wound of the head, fracturing the frontal bone to a great extent, on the evening of the fourth day had become delirious, and I hobbled to him (being lame myself from the same action) at the urgent request of one of his relations. I found the scalp over the forehead red, hot, and bound like a broad cord so tensely stretched over the injured parts beneath. The shot had penetrated near the centre and above the left orbit, and, proceeding obliquely upwards, fractured the os frontis near the frontal prominence of the right side.

I laid open the whole of the parts between the two points of fracture, and allowed a smart bleeding from several vessels to continue until his pulse became softened in character. He expressed great relief in a few minutes. The next morning his intellect was clear, and he made his final arrangements without difficulty, aware that I entertained scarcely a hope of saving him. The bleeding, I doubt not, contributed to the good result, but I have seen sufficient to feel convinced that no bleeding alone would have produced such prompt and decided amelioration.

With respect to fractures, you must remember that the skull is composed of an outer and inner lamina or table of bone, and that between these two there is a cancellated structure termed the diploe. This, at some periods of life, and at different parts of the bone, is of considerable thickness, and in some heads much thicker than in others—thus the outer table may be pressed into the diploe, an actual depression on the outer surface exist, without the slightest change of place in the inner. External depression, even when it exists, then, is not an indication for trephine.

Nay more, if actual displacement shall have taken place, you are not authorized by experience in performing any operation in the absence of symptoms indicating injurious pressure on the brain; for many cases are on record of extensive depression without bad consequences. There are two exceptions to this rule: when an external wound already exists, if depression is evident, the lever may

always with propriety be employed to raise the depressed portion. You will meet with fractures, however, where the point of the lever cannot be introduced. In such a case, wait for symptoms, if none be present, indicating pressure. 2dly. When foreign bodies are introduced in such cases, it should be a principle always to extract them, if within reach, with the least possible delay. Instances there are of balls and other foreign bodies lying imbedded in the brain, and harmless, for years: they are, however, very rare, and, from my own tolerably extensive experience in these injuries, to which I have always paid great attention, such favourable cases I know to be only exceptions, and therefore give you the rule absolute—always, without loss of time, but with the least possible disturbance, remove any foreign body if it be within reach, using the trephine, if necessary, to enlarge the opening. To this subject, however, I shall return hereafter, in connexion with injuries of the brain.

In a case where you distinctly ascertain depression, when all the attendant symptoms indicate injurious pressure, you then proceed, by a crucial incision, to obtain space necessary; and if you cannot by the lever raise the depressed portion, either the trephine may be applied or Hay's saw, according to the nature of the fracture and the result you wish to obtain, merely acting upon one principle—to remove the least possible quantity of bone—to effect it with the least possible disturbance of surrounding or subjacent parts. Particular directions respecting these operations I reserve until I have the opportunity of demonstrating them on the body.

Gentlemen, I will give you a last and conclusive argument against all operations of the nature of trephine, unless imperatively indicated; and that is, that they are generally fatal. I do not mean the mere operation itself is of such a nature as to produce death, but that the injuries requiring them produce so much mischief as seldom to give the operation a fair chance, and that the injury of the operation superadded to the original, no doubt contributes to the unsuccessful issue. The fatal result of all cases in which the trephine was used at the Hôtel-Dieu, was so constant, that in Desault's time he entirely abandoned it.

This I do not recommend; it is im-

peratively indicated in many instances, and often is the means of saving life; therefore, as to the numerous cases in which it fails, having once ascertained that it offers a chance of life which the patient would be deprived of without, your rule of conduct is perfectly clear; and he must be wanting in knowledge, or wanting in moral courage to do his duty, who hesitates. The following conclusions may be deduced for your guidance, from the considerations and facts now brought forward:—

1. The importance of fractures of bones of the head is dependent upon injury, primary or secondary, to the contents of the skull; indicating the principle of practice, that in all injuries of these bones the utmost care and vigilance is required in the treatment, local and constitutional.

2. That simple fractures without displacement give no diagnostic signs apart from the constitutional symptoms.

3. In all injuries of the head, when fracture is either ascertained or doubtful, remove the hair, apply cold, and cleanse the bowels.

4. If inflammatory or erysipelatous action, or suppuration under the scalp, supervene, free incisions should be made, to give vent to any matter, relieve the tension, and cause free local depletion—unless counter-indicated by the patient's pulse.

5. The trephine is only admissible when the symptoms indicate injurious pressure, or when there is a foreign body *in situ*. Mere depression of bone does not indicate such an operation. When there is a wound, and the bone can be raised by a lever, it should be done at once, and without hesitation.

CASES, WITH OBSERVATIONS.

By DR. HUGHES,

Physician to the Surrey Dispensary.

Empyema.—There are, perhaps, few diseases the diagnosis of which has been more assisted by the discoveries of Avenbrugger and Laennec; and there are, perhaps, none in which a mistake may more seriously affect the reputation of the practitioner, and sometimes even the life of the patient, than empyema. Before the employment of percussion and auscultation, the operation of paracentesis was not unfre-

quently performed by even good and experienced surgeons without the liberation of fluid. It sometimes happened that the disease had no existence except in the mind of the surgeon, and that fatal consequences resulted from his mistake. When, indeed, the indefinite nature of the symptoms, which were formerly considered characteristic of the complaint, are regarded, little surprise will be felt at the occasional occurrence of such mistakes. Fixed pain, laborious breathing, incapability of lying on the sound side, enlargement and fluctuation of the diseased side, and a dry, tickling cough, are given as the indications of the existence of the disease. It must be well known to every accurate observer that these, or most of these symptoms, may be dependent on other causes than empyema; and also that this disease may exist when the majority of them are absent. *Pain* is always an uncertain symptom, as it can be judged of by the physician only from the representation of the patient. One person will complain considerably of that which another will mention merely as uneasiness, and which a third will totally disregard. If complained of by a person supposed to labour under empyema, it may arise from recent pleuritis, rheumatism, neuralgia, or, according as it may occur on the right or left side, on congestion of the liver, hepatitis, cardialgia, &c. *Laborious breathing* is of little value as a diagnostic of this complaint, as it exists in a variety of other affections, and may depend on chronic bronchitis, emphysema, or oedema, or hepatization of the lung, hydro-pericardium, hydro-thorax, &c. Considered alone, therefore, it is of little importance as a diagnostic. *Incapability of lying on the sound side* also is present in other diseases, as in enlargement of the liver, consolidation of the lungs from pneumonia, and phthisis, and is by no means universal in empyema. It sometimes happens, from the fluid being confined to a particular situation by local adhesions, or other causes not easily explained, that the patient lies most easily on the sound side, as I have myself observed in more than one instance. It must also be recollected that the position which is generally assumed by persons affected with this complaint, as most agreeable, is that of supination, with only very slight inclination to the diseased side.

Enlargement of the affected side may be really present, or may exist in appearance only, and in both cases may arise from other causes. Enlarged liver and natural conformation may be the cause of the increased dimension in one case; and curvature of the spine, or contraction of the chest from old pleuritic adhesions, may induce a semblance of it in the other. But if the empyema is general, if the fluid is not confined by adhesions to a particular part, a long period may elapse previously to perceptible enlargement of the side. For as the spongy tissue of the lung is much more easily compressed than the parietes of the chest are dilated beyond their ordinary state of expansion, little or no increase in size will occur till the fluid has accumulated in quantity sufficient to compress the lungs to the utmost. *Fluctuation of the diseased side* I believe to be by no means frequently observable in empyema, and if present, may arise from abscess of the liver, as in a case related by Dr. Townsend; or from diffused abscess of the integuments. *Frequent tickling cough* so much more frequently depends upon other causes, as phthisis, irritable bronchial membrane, or gastric irritation, than upon empyema, that it can obviously be but of little importance as a diagnostic of the complaint last mentioned.

Individually considered, then, none of the symptoms mentioned are characteristic of empyema. It may, however, be said, that collectively they are sufficiently indicative of the existence of the complaint. Though when all of them are present, this certainly may, in the majority of cases, be correct, experience has abundantly proved that it is not so in all. The physical signs will, in cases of doubt and difficulty, if taken in connexion with the general symptoms, almost universally lead us to a correct diagnosis. The physical signs of empyema, in addition to enlargement of the side, separation of the ribs, descent of the diaphragm, and dislocation of the heart, which are not always present, and rarely appear in an early stage of the complaint, are great dulness on percussion, distance or absence of the respiration, deficient resonance of the voice, and an absence of that trembling vibration communicated by the reverberation of the voice to the hand when placed upon the parietes of the chest. These signs will be coextensive with the quan-

tity of the effusion, and may coexist with bronchial respiration, sibilous rattle, or even a certain amount of respiratory murmur in other parts of the same side, and with puerile respiration of the healthy side. Though these signs may at first sight appear by no means pathognomonic, as under certain modifications many of them are also present in other diseases, they will, I believe, when attentively examined, be almost a certain guide to the experienced auscultator, who is well acquainted with the general features of disease. The affections which, from a similarity of physical signs, are most likely to be confounded with the complaint under consideration, are, consolidation of the lung from pneumonia, and phthisis pulmonalis, and enlargement or abscess of the liver. From pneumonic consolidation it may be usually distinguished by the greater degree of dulness; by the almost perfect or entire absence of respiration in the part affected, which in hepatization almost always affords bronchial respiration and soft crepitating or mucous rattle; and by the character of the voice, which is trembling and shrill if the fluid is in a thin layer, and which, gradually decreasing in force as the fluid accumulates, is scarcely audible when it exists in considerable quantity; while, in consolidation of the lung, it is increased in intensity, without being materially altered in character. By placing the hand also upon the diseased side, a striking difference will be observed. If the dulness depends upon fluid, the natural vibration communicated by the voice to the parietes of the chest will be lost, while in hepatization of the lung it will be increased. In phthisis the dulness is, I believe, never so great, and the absence of respiration never so complete as in empyema. Should any doubt, however, exist on this head—should the dulness in the lower part of the chest be so considerable as to cause any difficulty, that doubt will be removed, and the difficulty solved, by further examination. Empyema commences generally below, and proceeds upwards; phthisis, on the contrary, begins almost uniformly in the apex of the lung, and progressively affects the inferior parts of the organ. It will therefore be found that, when considerable dulness—the result of tubercles—exists in the base of the lung, the disease in the apex will al-

most certainly be so far advanced as, by the presence of gurgling, amphoric respiration, or pectoriloquism, to enable the physician easily to decide on the nature of the complaint.

Enlargement and abscess of the liver will be best distinguished by the previous history and general symptoms, as I believe there are cases, particularly of the latter disease, which present exactly the same physical signs as empyema.

I have hitherto referred only to those examples of pus in the chest, in which the whole sac of the pleura is, or may become, involved in the disease; but it is in the local forms of the complaint—in those cases in which the fluid is confined to a certain space by old firm pleuritic adhesions—that percussion and auscultation are especially valuable as means of diagnosis. It is in such cases, I believe, that paracentesis may be performed with the best prospect of success, if practised with the view of curing the complaint; and in such cases, if the fluid has not already caused local distension, the physical signs afforded by percussion and auscultation can alone direct the operator to its exact situation. It may also be added, that it is by the physical signs alone that those cases can be distinguished in which the fluid is confined between the lung and the mediastinum or diaphragm, and an unnecessary and dangerous operation consequently avoided. It is, I think, highly probable that among the many instances in which paracentesis has been performed without the escape of fluid, the want of success has depended not so much upon an incorrect diagnosis, as upon the trocar being introduced in a situation marked out by authorities, rather than in the part indicated by dulness and want of respiration. The following case, though brought forward chiefly on account of the remarkable condition of the duodenum, is a good example of the ordinary form of empyema.

Samuel Robins, aged 44, came under my notice as a patient of the Surrey Dispensary, in October 1838. He was by occupation a lighterman, the father of six children, and of very temperate and industrious habits. His complexion was dark; a hectic flush was constantly on his cheeks; he had a frequent short cough, accompanied with muco-purulent expectoration; his respiration was hurried; his pulse small,

frequent, and feeble; nocturnal perspirations were general, and emaciation was slowly progressive; his appetite good, evacuations natural, and spirits excellent. Without any attentive examination of his chest, I supposed him to labour under phthisis, and treated him accordingly. For some time he appeared to derive much benefit from mild expectorant tonics, and blisters to the chest, with a narcotic at bed time. After about a month, however, he was so reduced in strength as to be confined to his bed. I then for the first time examined his chest by auscultation and percussion, and was informed of the following particulars of his previous history. About six years before he had suffered from an abscess in the leg, but had not been in any way inconvenienced in consequence after its speedy cure; and for about twelve months before I saw him he had been affected with a trifling cough. With these exceptions he had been in the enjoyment of excellent health till about eight weeks previously to my visit, when, after lifting a heavy weight, he felt a severe pain in the right side, for which he was cupped and took some medicine with relief. He afterwards felt frequent "flutterings and palpitations in the stomach," and suffered from severe vomiting, both of which were, after a week, stopped by aperients and effervescent mixture. His general condition, notwithstanding, was not improved; he passed a little blood per anum, and his cough increased both in frequency and severity. He made an unsuccessful application for admission into an hospital, and afterwards became a patient of the Surrey Dispensary. On examination of the chest I now found the right side considerably enlarged, and the width of the intercostal spaces increased; it was also dull on percussion throughout its whole extent, and destitute of respiratory murmur, excepting at the apex of the lung; the voice appeared feeble and distant. On the left side the resonance on percussion and of the voice appeared natural, and the respiration was rather puerile. The sounds and impulse of the heart were rather feeble, and the rhythm natural. From this examination, the history, and the general symptoms of the complaint, I had no hesitation in deducing the following diagnosis:—"Empyema of the right pleura; no important disease of

the left side of the chest; there exists no physical sign of tubercles in the lungs." He now was generally in bed, lying on his back, rather inclined to the right side, and he suffered from dyspnoea when he turned to the left side. His cough was not very troublesome, nor was he, when quiet, inconvenienced by difficulty of breathing; he suffered no pain, slept well, and ate heartily. He was ordered repeated blisters to the right side, and small doses of the milder preparations of mercury, in addition to his other medicines. The effusion notwithstanding progressively increased, and the little respiratory murmur heard in the apex of the right lung soon altogether disappeared. About seventeen days before his death he began again to complain of "fluttering and palpitation" in the umbilical region and scrobiculus cordis. This was in a few days succeeded by paroxysms of pain in the same part, at first recurring once in eighteen or twenty-four hours, and so severe as to destroy his rest and to exhaust his strength. The abdomen was repeatedly and carefully examined, but no tenderness, hardness, or tumor, could be discovered; a little flatulent distension alone appeared to exist; he had no sickness; the tongue was not red, but moist and very slightly furred; the bowels were easily acted upon by castor oil, and the evacuations were tolerably healthy; his urine was rather scanty, loaded with salts, and not coagulable by heat. Hyoscyamus and camphor, morphia, hydrocyanic acid, and opium, galbanum pill and opium, with fomentations and mustard poultices, were successively but ineffectually tried for his relief; but he appeared to derive a little temporary benefit from draught of liq. opii sedativ. and sulphuric æther. The paroxysms nevertheless soon increased in severity, frequency, and duration; they came on at irregular intervals, and appeared to have no connexion with his meals. His diet was frequently changed without advantage, and his abdomen minutely examined without discovering any cause for his sufferings. His appetite now began to fail, and his powers began to sink rapidly. About a fortnight after these severe paroxysms of pain appeared, I, on one occasion, found him with a coated tongue; a hot skin; a frequent, sharp pulse; and a tender, swollen state of the abdomen; all of which

symptoms had appeared the night before, after a fit of greater than ordinary severity. Eight or ten leeches and hot fomentations were ordered to be immediately applied, and calomel and opium to be administered; but he expired in one of the paroxysms, before either had been obtained, about the middle of January 1839.

Inspectio cadaveris, 20 hours after death. — External appearances:—The body was considerably emaciated; there appeared an unnatural roundness and fulness of the right side of the chest, and some distension of the abdomen. The head was not opened. Chest:—The right pleura contained about three quarts of thick yellow sero-purulent fluid, and was lined with a soft, uneven, flocculent membrane, two broad bands of which passed between that lining the parietes to that covering the diaphragm. The right lung, about the size of a healthy spleen, firm, purplish black, and quite destitute of air, was confined by adhesions to the posterior mediastinum and spine. The left pleura and lung were healthy, with the exception of a little emphysema in the apex of the latter. The bronchial membrane was also thick, turgid, and opaque. The heart and pericardium were free from disease. The peritoneum was not much injected, but contained a few ounces of turbid purulent serum. The convolutions of the intestines were adherent by very tender, recently effused false membranes, some shreds of which were also found upon the convex surface of the liver. The mucous membrane of the stomach was soft, thick, and discoloured in patches, and presented marks of former ulceration. The pylorus was thick, hard, and semitransparent; but the opening through it was not at all contracted. Connected with the duodenum was now discovered a tumor nearly as large as the adult fist, arising from an enlargement of the head of the pancreas, and adhesion of some neighbouring intestines. It was unfortunately cut in removing it; but, on attentive examination, it was evident that not only was the right extremity of the pancreas enlarged, and softer and less distinctly glandular than natural, but that it had ulcerated into the duodenum, a portion of the natural parietes of which, to the extent of about three inches square, had entirely disappeared, the deficiency being supplied in part by the head of

the pancreas, and in part by adventitious structure, like condensed cellular membrane. Beyond this, the mucous membrane terminated in a smooth rounded fold; and about an inch from this fold was a circular spot, the size of a shilling; from which the mucous membrane had been entirely removed. The edges were here also rounded, smooth, and even, and the surface quite healed. Both appeared to be of considerable standing. The pancreatic and common cholelodic ducts terminated upon the new surface of the duodenum, about three quarters of an inch apart. They appeared healthy, as were all the other organs of the abdomen.

The condition of the duodenum in the preceding case is not only unusual, but when regarded in connexion with the symptoms existing before death extremely difficult of explanation. The circumstances which create a difficulty in understanding the progress of the complaint are the following:—Every portion of the ulcerated surface was perfectly healed; the disease, therefore, was of considerable duration. The man had enjoyed uninterrupted good health till about five months before his decease. The symptoms referrible to this complaint were apparently very disproportionate to the great extent of the disease. He had suffered in the early part of his illness only from a feeling of “fluttering” at the scrobic. cordis, and some not very severe vomiting, both of which were removed in a week by aperients and simple effervescent mixture, and it was not till rather more than a fortnight before his death that he was attacked with paroxysms of severe pain occurring at irregular intervals, and unaccompanied with vomiting, costive bowels, diarrhoea, loss of appetite, or any other symptoms of serious affection of the alimentary canal. When, conjoined with these facts, it is recollected that rapid emaciation, a state of constant suffering, almost continued vomiting after taking food, and its frequent occurrence at other periods, not uncommonly result from very slight ulceration of the mucous membrane, the circumstances connected with the case related are, I think, not easily explained or even understood. I must also confess my inability to comprehend the cause of the paroxysms of severe pain which my patient suffered several days before his death, as,

though they were without doubt in some way connected with the disease of the duodenum, or the adhesions and contractions resulting from it, they were never affected by the time of taking or by the quality of his food, and were unaccompanied with the symptoms usually attending extensive disease of the stomach and bowels. In reference to the empyema, it may perhaps be inquired why, seeing the symptoms of the disease were so decided, the operation of paracentesis was not performed. In reply to this supposed inquiry, I observe, without intending either to deny its desirableness or necessity in some cases, or to enter at any length into a consideration of its efficiency as a means of cure, that from the recorded experience of others, from my own observations, and from circumstances connected with the pathology of the disease, I am induced to believe that the operation of paracentesis in empyema is not generally to be recommended for the purpose of cure; that the disease should be attacked by constitutional and milder topical remedies; that this should be the rule of treatment; that paracentesis should be the exception; and that this exception is indicated by certain peculiarities in the history of the case. I am aware that the operation is favourably regarded by some practical men, and that in a note attached to the article “Empyema,” by Dr. Townsend, Dr. T. Davies has given a table of ten cases in which the operation was performed, of which only two died*. But I am also aware that many cases recover without the adoption of this extreme measure. Dr. Stokes states that he alone has seen twenty examples of recovery without operation. I have myself very rarely, if ever, seen a perfect recovery after paracentesis had been performed, or, indeed, a favourable termination, unless in those cases in which the fluid was already making its way externally. Nor, indeed, can I suppose that a perfectly favourable issue can often be reasonably expected when the condition of parts involved in the disease is examined. In many cases there are several quarts of fluid effused; the fluid itself is of an unhealthy character—im-

* It should be observed that five out of these eight successful cases were under six years of age; that all the cases of pneumothorax and hydrothorax were unfortunate; and that the *grand total* is eight recoveries to fourteen deaths.

pure pus—turbid sanguinolent serum—or a combination of the two; the parietes of the sac are not merely lined with false membranes, but often coated with thick layers of flocculent unorganizable lymph; the lung is compressed—bound down by adhesions, and incapable of future expansion; the ribs have in some degree lost their elasticity; and the diaphragm has become in some measure paralyzed. An immense unhealthy chronic abscess is, in fact, the disease to be treated; and it is, moreover, an abscess the walls of which are incapable of collapsing, and from which, therefore, if the fluid is withdrawn, the space previously occupied by it must be in some measure filled by air. A simple case of empyema is, therefore, by operation converted into one of pneumothorax. The presence of air alone often induces fresh inflammatory action, the constitutional effect of which is sometimes sufficient to destroy the little remaining power of the patient. From the pressure being removed from the extremities of the vessels, the effusion will progress more rapidly, and, as in dropsy, reaccumulation may be expected in a comparatively short period.

I regard the disease, then, as a large chronic abscess, the walls of which cannot be approximated; and I believe there are few experienced surgeons or pathologists who would recommend such an abscess to be opened, or who would not rather advise general and topical remedies to be employed for the purpose of effecting absorption. There are, however, some cases in which I imagine the operation may be advantageously performed, with the intent of curing the complaint. They are those in which fluid has been rapidly effused from severe inflammation, whether arising from common causes or accident; in which the sufferer is young and of good constitution, and in which, both from the short duration of the complaint and from the signs afforded by percussion and auscultation, it may be fairly presumed that the lung is capable of expansion. In such cases it is possible, that after all acute inflammation has been reduced, the trochar may be employed with benefit. Yet it must be recollected that even such cases not unfrequently terminate favourably, without very active interference, although the inflammatory product should not be en-

tirely absorbed. The following case may be quoted as an example:—

CASE.—R. Hockwood, aged 26, a chimney-sweeper, of intemperate habits, received a severe blow on the left side, on Christmas eve, 1836. He suffered considerable pain in consequence, for some days: little or nothing, however, was done for his relief till I saw him, nine days after the accident, when he presented all the general and local symptoms of subacute pleuritis, with considerable fluid effusion. The lower part of the left side of the chest was tender on pressure, and exceedingly dull on percussion; the respiration was entirely inaudible, and the voice was distant and feeble below, but became somewhat shrill and trembling as the stethoscope was passed upwards. The superior part of the left, and the entire right side, appeared healthy. He was bled, cupped, frequently blistered, and mercurialized, with benefit as regarded his general symptoms and his local sufferings, but without the effect of removing the effused fluid. In about six weeks or two months, three or four chronic abscesses appeared in the vicinity of the scrobiculus cordis and the diseased side. They burst, discharged some healthy pus, and healed spontaneously. In about ten days after this, a more diffused swelling attracted notice, over the cartilages of the superior false ribs. This was not interfered with, and in a few days it also burst, and discharged a considerable quantity of sero-purulent fluid. A tent was introduced into the wound, to prevent its healing, and a poultice applied.

The cough, which had hitherto been pretty constant, was much relieved, and the local uneasiness decreased. For several weeks the wound allowed the gradual escape of fluid. It afterwards healed and opened several times. When there was no opening, or one not sufficiently large to allow the escape of the fluid, the cough generally became more troublesome, and muco-purulent matter was freely expectorated. I was, however, never able to discover any decided evidence of communication between the pleura and the bronchial tubes. He now and subsequently suffered very little from his complaint. I administered tonics freely, and allowed him a liberal supply of nutritious diet; and after several months, as his strength was restored, as he had

but little cough, and there was very little discharge from the wound, I discontinued my attendance. I have since heard, that about a week after I ceased to attend him, the wound spontaneously healed, and has now for seven months caused him no inconvenience, and that he has been constantly engaged in his trade. I saw him on the 7th instant, when he told me he was as well in health and as strong as at any former period of his life, though he had still some cough, accompanied with expectoration, which was occasionally tinged with blood. He appeared quite as stout and vigorous as when I first saw him, more than two years ago; and from his thick coating of soot, must, I supposed, have been that day actively engaged in his business.

But though the operation may be rarely advisable as a mode of cure, it may be exceedingly important as a remedy for the relief of distressing symptoms—as when a considerable accumulation of fluid, by its pressure on the healthy side or upon the heart, causes great dyspnoea and an intolerable feeling of suffocation. In such cases, it is evident that a small quantity of the fluid may be removed, not only without injury but with very great advantage. In the case which has given rise to these observations, I supposed that the lung had collapsed, and, by being covered with lymph and bound down by adhesions, was incapable of future expansion. The examination after death proved the correctness of this opinion. I therefore thought that the operation for the purposes of cure was not warrantable, and that as the patient really appeared to suffer very little from the presence of the fluid, and never, on a single occasion, complained of any inconvenience in consequence of, or directed my attention to, the disease of the pleura, I considered that with the view of affording him temporary relief it was unnecessary.

But there are circumstances in which empyema has appeared to me to be rather advantageous than otherwise; if, indeed, the mere continuance of life in a hopeless state of disease may be considered an advantage. The prognosis of empyema is, of course, rendered more unfavourable by the co-existence of phthisis; but I have, on more than one occasion, had reason to believe that the life of patients labouring under phthisis

has been unexpectedly prolonged, and that the progress of the complaint has been notably retarded by the occurrence of empyema. Dr. Stokes has already remarked the arrest in the progress of some cases of phthisis by the occurrence of pneumothorax and empyema, and has related the case of a patient who lived for thirteen months after the existence of pneumothorax had been clearly established. A much more remarkable case, however, has lately occurred in the practice of my friend and colleague, Dr. Barlow. Here the patient, a young woman, though she was, when first seen by him, apparently in the last stage of phthisis, lived (and generally in a tolerably comfortable condition) for *three years and a half*. When she first came under his care, there existed decisive evidence of pneumothorax and empyema, as proved by metallic tinkling and splashing of the fluid, which was distinctly heard by the patient and her friends, as well as by her medical attendants. During three successive summers she gained flesh, and occasionally walked out; and during three successive winters became seriously ill, and was confined to bed. When, at length, she died, one lung was found to be perfectly useless for the purposes of respiration, being reduced, by previous ulceration and compression, to a very small size, and being perfectly solid, and incapable of admitting air. The other lung was almost entirely occupied either by phthisical cavities or softening tubercles. A very small portion of this lung was alone crepitant, and death appeared to have at length resulted from this portion having become œdematous.

What has been observed by Dr. Stokes, and was so entirely confirmed by the remarkable case of Dr. Barlow, in reference to phthisis and pneumothorax, has appeared to me to be equally true respecting phthisis combined with empyema. The cause of this retardation of disease, at first sight, appears sufficiently easy of explanation; but I believe that upon more minute consideration it will be found not unaccompanied with difficulties; but for the present, at least, I must defer any examination of his subject.

CASE OF POISONING BY GIN.

To the Editor of the Medical Gazette.

SIR,

I BEG to inclose notes of the case of poisoning by gin, alluded to in the LONDON MEDICAL GAZETTE of the 11th ult. and shall be obliged by your giving them a place in a forthcoming number, should you consider them of sufficient interest.—I remain, sir,

Your obedient servant,

W. D. CHOWNE, M.D.

14 a, Princes Street, Cavendish Square,
May 13th, 1839.

March 17th, 1839.—A lad, of between 7 and 8 years of age, obtained access to a bottle containing some gin. In about twenty-five minutes after, he appeared to be slightly affected. He was left alone for a space of about five minutes, at the end of which time he was found lying on the floor insensible, with his nose bleeding. He was in such a position as to leave no doubt that he had fallen from a chair near the cupboard in which was the gin-bottle. The chair did not stand there when he was left alone, and he must have placed it there.

The lad, very soon after he was found, threw some fluid from his stomach, which, according to the statement of his father, smelled of gin. He was put into bed and kept warm, but no medical treatment was adopted.

At 1 o'clock P.M. (five hours after the spirit was taken) a medical man saw him. At this time, according to his father's account, the tongue appeared to swell, the child groaned and seemed dreadfully oppressed. The quantity of gin that he had taken was computed at half a pint. An emetic was given, and the child was put into a warm bath, but, neither producing any visible effect,

At 3 P.M. (seven hours after the spirit had been taken) he was conveyed to the Charing-Cross Hospital, where he became my patient, and was seen by me about fifteen minutes after his arrival; in the interim warm water had been passed into the stomach and withdrawn by means of the stomach-pump. The fluid had not the odour of gin, nor of any thing peculiar, neither was there the odour of gin in the breath.

The lad was perfectly insensible and

motionless; the limbs relaxed and powerless; the face pale; the general surface pallid, and below the ordinary temperature; the pulse very small, feeble, and 144; pupils contracted; the exclusion of light by the hand did not produce dilatation; the breathing was rather slow, difficult, and decidedly stertorous; there was involuntary urging of the stomach, by which a small quantity of fluid and saliva drained from the mouth; this had no peculiar odour. The bowels had not acted. Whether urine had passed was not known.

The child's general appearance conveyed the idea that he was sinking rapidly, except that the countenance was peculiarly placid, and free from the expression in persons in *articulo mortis*; indeed, the face did not correspond with the general symptoms, but formed a striking contrast to them.

He had three leeches applied to each temple, a purgative dose of calomel, a cathartic enema, an application of liquor ammonia to the scalp, a blister behind each ear, and mustard cataplasms to the feet: he had also a mixture of ammonia and camphor. He was placed with his head and thorax raised on pillows.

11 P.M. (fifteen hours after the spirit was taken.) The bowels have been opened, and urine passed, both without consciousness. The scalp red and slightly vesicated; the feet also red from the mustard cataplasm; the leech-bites bled moderately; general appearance the same; the breathing still stertorous, but with the addition of mucous rale in the thorax; the irides still contracted; the eyes shewing no signs of sensibility; the limbs still motionless and powerless; the skin prone to be cold; nothing elicited signs of consciousness; the pulse rather improved in strength, and still 144; the countenance still free from expression of anxiety, or uneasiness of any kind. The mixture to be continued; the body and extremities to be kept warm; the irritation of the scalp to be encouraged; and the elevated position of the head to be continued.

18th.— $\frac{1}{2}$ past 12 P.M. (twenty-eight hours after taking the spirit.)—The general appearance improved; the eyes occasionally opened, the pupils still contracted; no expression in the eyes of consciousness; the face and general surface still pale, and prone to be cold; the expression of the face still calm,

free from anxiety, and peculiarly placid; the paleness of the face not of a livid character; the stertor of breathing diminished, but the effusion in the air-vessels of the lungs increased; the mucous rale increased, and extremely audible over the whole chest; the limbs still relaxed; the pulse still small and rapid. The treatment to be continued, with light nourishment and coffee.

$\frac{1}{2}$ past 10 P.M. (38 $\frac{1}{2}$ hours after taking the spirit.)—The eyes open, still better; the pupils less contracted; the irides more mobile. There is a look almost of consciousness; face and general appearance as at the last visit; the stertor still less; the mucous rale not diminished; pulse rather firmer, still quick, 144.

19th.— $\frac{1}{2}$ past 12 P.M. (52 $\frac{1}{2}$ hours after taking the spirit.) The general appearance, at first sight, much improved; the eyes open quite well. The lad looks about him with seeming intelligence; and although he does not reply when spoken to, his declining to answer appears to be rather from disinclination than from incapability. The symptoms of coma have subsided in a very marked degree; the stertor still less than yesterday, and reduced to almost nothing; the lungs, however, appear to be even more loaded; the mucous rale extremely loud and general; the breathing rather shorter; cheeks rather flushed; skin generally hot and dry; pulse much more rapid, from 160 to 180, but still distinct. He continues to take his medicine, and occasionally some tea and arrow-root. Limbs still relaxed and powerless; shews no sign of volition. In this the contrast is very striking between the seeming intelligence of his look and the inactive state of his will. He does not make the least effort, although he looks as if he could do so without difficulty. Has passed motions and urine since last night, both involuntarily.

4 $\frac{1}{2}$ P.M. (57 $\frac{1}{2}$ hours after taking the spirits).—In nearly the same state as at last visit, except that the cerebral symptoms are diminished, and those connected with the respiration are increased, the lips slightly livid, respiration laboured. The mucous rale still more intense, and may be heard by bringing the ear near the chest, without contact of the ear or aid of the stethoscope.

To have a blister between the shoulders; rubefacients on the anterior part of

the thorax; to continue arrow-root, &c.

March 20th, 3 $\frac{1}{2}$ A.M. (67 $\frac{1}{2}$ hours after the spirit), he died.

Through the whole period there was neither delirium, injection of the conjunctiva, convulsion (or tendency to convulsion), peevishness, or even anxiety of countenance.

Post-mortem appearances, about twelve hours after death.

External appearances.—The scalp free from any appearances of injury. The surface of the body perfectly natural, and without discoloration. No appearance of injury any where. Expression of face placid.

Head.—On removing the scalp, no unusual redness discovered on its inner surface, nor any on the pericranium.

The dura-mater rather more tense than usual; the arteries more visible; the blood within them rather more florid; in other respects natural.

No morbid adhesions between the dura-mater and the arachnoid. No escape of fluid.

The tunica arachnoidea more than commonly vascular. No coagulable lymph or other product of inflammation. Very slight pearly appearances, but not enough to indicate that inflammation had taken place.

The veins of the membrane distended with dark blood; those corresponding with the temporal regions especially. The veins on the anterior part of the membrane full, as well as those of the other parts; the fulness, therefore, not the effect of gravitation after death.

Base of the Cranium.—On removing the brain, a very small quantity of fluid (serum, tinged with blood) in the fossæ of the base of the cranium; the quantity so small as to appear to be only what oozed from the vessels during the removal of the cerebellum: it appeared to accumulate during the process, the quantity not exceeding from two to three drachms.

The under surface of the brain natural. Upon making sections of the medullary substance, not more than the usual points of blood, nor indeed more than might consist with a healthy and vigorous state of brain in a child of the patient's age.

The quantity of fluid in the lateral ventricle natural; the vessels rather

fuller; the blood within them more florid; the plexus choroides more than commonly full and florid; neither coagulable lymph, turbid fluid, nor other sufficient sign of inflammation; the left lateral ventricle in every respect like the right; the other parts of the brain, including the cerebellum, healthy in appearance. No odour of gin, or any peculiar odour, in any part of the brain.

Chest.—No effusion or other sign of disease in the cavity of the pleura. The lungs on the parts first presented to view natural; the posterior and under parts dark and congested; the congestion probably commenced prior to death, and increased after from gravitation. There was no disease of the parenchyma. The trachea and bronchial tubes full of frothy, turbid fluid; the lining membrane of the air-passages natural, with the exception of a slight blush at the upper part of the trachea, so slight, however, as not to warrant any inference. The heart quite healthy; contained a small quantity of dark, coagulated blood, with some coagulated lymph. Scarcely a drachm of fluid in the pericardium: this was healthy.

Abdomen.—Neither serum, pus, nor coagulable lymph, in the abdominal cavity. The stomach empty; its outer surface rather paler than usual; no remarkable vascularity of any part; the inner surface uniformly pale, and free from patches or discoloration, except a portion about the size of a child's hand, near the cardiac orifice, with very small vessels visible in and under the mucous coat; the form arborescent; colour florid; this appearance, however, only such as is commonly seen, and such as may be the consequence of abstinence, or of the irritation of food; nothing beyond the vascularity of the part that resembled inflammation; the stomach in every other part healthy. The liver healthy. The gall bladder full and distended; the contents natural. Spleen and kidneys healthy. The intestinal canal natural; some parts more vascular and of deeper colour than the rest, but still presenting nothing that is not commonly found in most subjects.

Surfaces of the viscera.—On all the surfaces a tendency to dryness. Those of the brain, the lungs, the heart, and the intestines, becoming so dry immediately on exposure to the air, as not to communicate the least moisture to the finger.

HUMAN ANATOMY AND PHYSIOLOGY,

As understood by the Chinese.

By G. TRADESCANT LAY, Esq.

[For the Medical Gazette.]

AFTER some reflection upon the subject, the easiest hypothesis which I can frame, to account for the notions which the Chinese entertain respecting the parts and economy of the human system, is, that they are the fragments of a more perfect type (*ὑποτυπωσις*) or exemplar. My reasons for thinking so are these:—Firstly, they seem not for many ages to have opened a body; so that subsequent writers, when they attempted to transfer the views of more ancient writers into their own works, were liable to fall into the greatest mistakes, as having no experimental conception of the thing, either to set them right or keep them from going wrong. Secondly, they are not very careful in copying nor printing the books and plates illustrative of anatomical subjects, as will appear by a collation of several editions or abridgments of the same work. Thirdly, a little research among their antiquities has taught me that they made a good beginning in the rudiments of several sciences; among the rest, we find that they considered musical intervals, in reference to the lengths of a vibrating chord, or a column of air undulating in a resonant tube; and expressed their proportions arithmetically, or in numbers. They did not derive this knowledge from the Jesuits, because these intervals belong to melodies peculiar to their own instruments. I am, therefore, willing to allow that the ancient Chinese were better theorists than their descendants, and had some ideas of nature and truth to which the latter are strangers, and others which they have copied in a very confused and imperfect manner.

In a large Encyclopædia which I have, I see there is a classification of the different kinds of nose, mouth, and ears; but whether they had any thing like the science of physiognomy, I am not able to say with certainty, though I suspect they had, for they commonly detect the peculiar features in a stranger's character with amazing sagacity and quickness. Ill health has obliged me to play the truant with my Chinese studies, so that I have not been able to

look further into the matter. The same reason will render this communication a mere outline; yet I hope, as it is drawn from original sources, and not borrowed, it will not be unworthy of publication.

In describing the human skeleton, the Chinese take no notice of the bones in the wrist and ankle; and as to the phalanges of the fingers and toes, the radius and fibula of the forearm and leg, they seem to have been either forgotten or considered as unworthy of any mention. Some pains, however, are taken to represent the vertebræ, though they seldom exhibit the true number, but this is a small matter where such strange deficiencies exist. The atlas is represented in one drawing I have as very long, and is honoured with a distinct name. The spinal tube is well marked, and there is special reference to the spinal marrow, as running up from the os sacrum and expanding itself within a cavity in the head, which is called the *sea* or *conceptaculum* of marrow. If, for the sake of preserving an analogy with the lower animals, we consider the brain as a multifarious expansion of the spinal cord, this is not much amiss, if we can forgive the utter want of details. To call the brain or its cavity the *sea* is an ambiguous way of speaking, for the *sea* is the source as well as the repository of all the rivers; the latter, however, is more likely to have been the sense in which they used the term. Now if we consider the brain as the expansion of the spinal marrow, or rather (as comparative anatomy would seem to teach us) the aggregate of many pairs of nerves variously unfolded at their common termination or point of union, this way of speaking would be as true in philosophy as it is figurative in language. The true ribs, sternum or breast-bone, the clavicle, the scapula, though without the spine and its continuation, the acromion process, are tolerably represented both in figure and situation. Their ideas of the pelvis are of a multiform and proteus kind: sometimes it expands about the base of the abdomen, like the short tail or skirt of a vest; at others we see a diverging arm on each side below, to be articulated with the thigh-bone; and now and then a process depending between the thighs, which may be either the os coccygis or the two tuberosities of the ischium, as there are two points upon the lower edge; or any thing else a charita-

ble construction may allow. They are unfortunately two well acquainted with the shape and the important functions of the knee-pan; for by the removal of this they sometimes teach offenders the difference between good and evil. In the refinement of Chinese criminal legislation, every specific offence should be followed by a specific penalty, that the people may be instructed nicely in the great particulars of their duty; hence the variety, and, in our opinion, the atrocity of their sanctions.

The attention of the Chinese anatomist is mainly diverted to the structure and use of the parts within the trunk, for upon these all the vital functions depend, without any control or interference from the brain. Care is taken to mark the two passages into it—the larynx and pharynx, with their respective continuations, the windpipe and the gullet—the one as the *road* for the *air*, the other as the *road* for the meat and drink. The trachea is uniformly represented as having a certain number of rings from the top to the point where it enters the lungs, but without any bifurcation or bronchia. It passes through the lungs on its way to the heart*—a very compendious method of dispensing with the aid of four pulmonary veins, as the vessel or artery is simply a continuation of the trachea. We may therefore suppose that the air boldly enters the heart to mingle itself with the blood, instead of coquetting among the bronchial tubes and air-cells. The lungs are represented as having six lobes, two on one side and three on the other, with one in the middle; uniformity, however, is not always maintained in this respect. They are sometimes called leaves, and have the ovate or most common form of a leaf, for easier recollection. From the point where the trachea enters the heart, three tubes (?) issue; one goes to the spleen, another to the liver, and a third to the kidneys. I have put a query against the name tubes, because they are sometimes denoted by a term that merely implies a thread. We may assume, I think, that the old teachers had traced the connexion of these organs with the heart through the medium of the arterial and venous systems; but their successors,

* Gutzlaff, in his analysis of a Chinese medical work, calls the trachea the aorta, because it enters the heart.

remembering only the fact, without any of its circumstances, made short work of it, by joining or bracing them at once to the heart, just as in another place we see the correspondence between that organ and the principal air-passage is exhibited merely by extending the trachea till it enters a hole in the top of a kind of hemispheric lid. In a figure given among the illustrations of a Japanese Encyclopædia, belonging to Mr. Medhurst, these tubes, with the œsophagus, are represented as passing through a plane, which we may suppose is meant for the diaphragm, with their appropriate names placed just under the point of transit.

The spleen seems to have been regarded as an important auxiliary to the stomach in the business of digestion; perhaps as acting the part of a secreting organ; hence it is displayed as lying upon the top or dorsum of the stomach, with the omentum hanging like an apron or lappet from it. Now there has been such a diversity of opinion respecting this organ among ourselves, that we may easily let the Chinese enjoy their own views about its functions, though I have little doubt but comparative anatomy will in time help us to a right conclusion. My attention has been on several occasions directed to the Medusæ and their related groups, with the view of improving my ideas of their structure, arrangement, and general history. In most of them we find a number of ampullæ, cæcal appendages, or blind worm-like vessels. In some, these form a conspicuous and beautiful object; in others, the aid of a strong magnifier is necessary to bring them to light. As these are connected with the anastomosing system of circulation, I apprehend that they serve as depositories of the nutrient fluid, which reservoirs in them till it is animalized, or has acquired a tendency to organize. May not the blood during its sojourn in the spleen undergo a change somewhat analogous to that when it is forced back towards the stomach through the *gastria inferior* and *vasa brevia*? if such a supposition is admissible, it is in a state better fitted for secreting the gastric juice. If this view of the matter be just, our Chinese physiologist was not far from the mark in his guesses, when he called it a *viscus* that *waits upon* another.

The stomach is represented as extending from the back towards the belly. The cardiac entrance and the pylorus have each of them an appropriate name; the former, towards the back, is called the bulged or swollen entrance; the latter, a little above the navel, the secret passage, from its comparative smallness. There is no notice taken of the duodenum, so that the *ductus choledochus communis* has no existence. The pancreas is in the same predicament, such care have they taken that man should have no resemblance to some of the finny tribe, where this organ attains a prodigious size. We are at once, then, without any ceremony introduced to the *small intestine*, which winds about an imaginary navel or axis in a very elegant manner. It is connected at its lower end by a peculiar *joint* to the *large intestine*, which winds about a perpendicular line of rotation in the same manner, and differs from the former only in having a larger bore. If these be considered as the *jejunum* and *ileum*, we have no representative for the colon, and its appendage—the *cæcum*, for the *large intestine* terminates in the *straight intestine* or *rectum*. The *joint* or point of communication between the large and small intestine deserves no small degree of emphasis, because it is from this ring that a halitus oozes out, which is collected by the urinary bladder, and then becomes properly urine. The words used to convey this statement are charming and appropriate; one could only wish that they had been used to a better purpose. The urinary bladder is usually represented as very large, with its fundus towards the point of junction between the two different kinds of intestine, and half concealed by the latter, while it terminates in a neck resting upon the pubes.

The generative fluid is secreted, it would appear, by the kidneys, and conveyed towards the pubes by a canal, that is differently represented in different figures. The *vas deferens* is represented as issuing underneath the urethra, but no notice is taken of their union. The Chinese castrate the males, and spay the females, among their domestic animals; and I believe the former is a punishment for those who have been more free than welcome with the royal concubines; but they do not attempt to remove the

kidneys, but set about the operation in a way much more pertinent to their purpose. The doctors only have the privilege of being dunces in this matter.

The liver has five leaves or lobes, upon one of which the gall-bladder rests, and I suppose communicates with the heart through the liver, to which it is attached.

I forgot to mention that the brain and spinal marrow are said to be within the domains of the kidneys, from which, I suppose, they imagine that the medullary substance is derived. A people unspeakably more acute and inventive than the Chinese knew nothing of the lacteals, but supposed that the chyle entered the liver by the common passage, and was from thence conveyed into the heart through the vena portarum. It is therefore no wonder that the Chinese should be ignorant of their existence.

The most perplexing and least satisfactory part of their anatomical outline is the circulation: first, because the tubes conveying the vital fluid are not traced to the heart; and secondly, because these tubes are distinguished by terms that have no clear and distinct meaning assigned to them. These terms are not strangers to those who have read a little about Chinese literature; yet among Chinese students I have not met with any who could give me more than an approximate definition of their meaning. The *yang* and *yin*, "light and darkness, male and female;" but what has this to do with the circulation? Light and darkness rule by turns throughout the mundane system, and male and female run throughout the most remarkable orders of animated nature; but in the microcosm of man, one would be glad to know under what modality they subsist, for we are not in quest of words but ideas. Our case is not, however, quite desperate, for if we traverse in our minds the different phenomena in which they are said to apply, we shall get the general and reciprocating ideas of *giving* and *receiving*. The sun bestows light, the moon receives it. In the sexual intercourse among animated beings, and by a similar provision in vegetable fecundation, the same ideas of giving and receiving obtain. If we apply them to the circulation, we have

a proper distinction between the arterial and venous system: one gives the blood, the other takes it away; and *yang* will be an equivalent for arterial, and *yin* for venous. If we go a step further, and say, for the convenience of speech, that we have a secreting or glandular system on one hand, and a lymphatic or absorbing system on the other, the ideas *yang* and *yin*, *giving* and *receiving*, obtain in like manner. In this way I bring things to an issue; my statements are either true or false, and may be dealt with accordingly; they are not nonsense, which is the most untractable thing in the world.

To explain their views of the circulation as well as I am able, I will then take it for granted that *yang* meant arterial blood, with all the healthy secretions from the glands; *yin* venous blood, with the absorbent system. In this circulation or general economy of functions, the kidneys, bladder, gall-bladder, liver, spleen, and the *san tseaoi*, to be adverted to presently, take a part either mediately through the heart, or directly, by particular tubes and canals; and here they fairly leave us in the lurch; for though we see vessels running from the fingers, toes, sole of the foot, in their appointed courses, and terminating upon the breast, under the arm, under the ear, near the site where the temporal artery is felt, at the internal and external corners of the eye, and upon the upper lip, we have neither words nor descriptive plates to tell us what way they communicate with the several internal organs. Here is a gap to be filled up by conjecture and inference in the best way we can. This I will do shortly, lest I should weary without instructing, by supposing that the kidneys, liver, and spleen, stomach, small and large intestines, &c. were considered as sending their contingents of *yang* and *yin*, positive and negative, first to the heart, and then all over the system. The theory may be exhibited in the short table annexed.

From this draught it will appear that the principal viscera in the trunk were regarded as having each a several share in the general economy of the human body by means of vessels that were arterial or secreting, *yang*; venous or absorbing, *yin*, through the medium of the heart, or centre of the circulating

| Tubes | run from the | to the | | | |
|-------------------------------------|---|--------|------|---|------|
| Yang ming Tae yang Seaou yang | Great intestine Small intestine Three tseou | } | Hand | | |
| Yang ming Tae yang Seaou yang | Stomach Urinary bladder Gall bladder | | | } | Foot |
| Tae yin Keue yin Seaou yin | Lungs Crown of the heart Heart | | | | |

Through the heart.

system. For its consistency with truth, or with itself, I make not myself responsible, but all the while assume that it is at best a sorry travesty of what was once an approximation to nature and reality. The qualifying epithets, *tae*, great; *seou*, small; *ming*, clearness or sheen; *keue*, dichotomized, or like the moon in her quadratures, have a reference, it would seem, to the size and form of the bore compared with the whole diameter of the tube. This indicates that some of the old teachers had observed the differences between the coats of the arteries, veins, lymphatics, ducts, &c., and thrown them into a kind of classification, while their scholars have faithfully preserved the names without any specific notion of the thing.

The *san tseou** are not represented, because the moderns say they do not know their figure. From some loose expressions I am encouraged to suppose that the right and left auricles, and the aorta, were the three (*san*) things originally referred to as forming three important points upon the venous, arterial, and pulmonary vessels of circulation. I will not insist upon this view, but shall be willing to give up my opinion when I can find a plausible reason for so doing†. The generative fluid is

produced by the action of the heart, followed by that of the spermatie orifice, and a secretion or distilment from the air or oxygen of the *san tseou*. The vital air is supposed to traverse the whole system, not as it does in the tracheæ of insects, but in combination with the blood—a circumstance I ought to have mentioned before.

The nervous system, if it ever entered their notions, was doubtless confined to the sympathetic and intercostal. Man had no more dignity in this respect than a snail, or any other molluscos animal, where the nerves run up and bulge out into little knobs or ganglia about the œsophagus. All the resolves of the will, as well as the evolutions of feeling, had their seat within the trunk, whence the threat, “he shall not enjoy quietness in his belly.” Among the Chinese the heart is the reputed tabernacle of the spiritual part, but the other viscera contribute their quota in the functions of the mind, some of them in a way that is altogether material, as the *san tseou* and urinary bladder, for example. To assign to each one of them in theory their proper office is a fundamental point in this part of abstract philosophy, and constitutes the portal that introduces us into the temple of their *mataphysics*. I had been led to suppose that they had not the elements of this science till I found traces of it in their medical and anatomical works. Its development will form a curious subject of research if health and life last, for if it is valuable for nothing

* There is a remark upon one of my anatomical plates that can only apply with any thing like truth to the ureters, vesiculae seminales, and prostate gland, which, after all, perhaps, may be the organs in question.

† From an expression under my eye, which, in the elegance and fullness of the language, seems to refer to ducts and fluid, the *san tseou* may refer to the pancreas.

else than antiquarian interest, it will be worth investigating.

The order of the lungs and large intestine is gold; the order of the heart and small intestine is fire; the order of the liver and gall-bladder, wood; the order of the spleen and stomach, earth; the order of the crown of the heart and the *san tseon*, water. In the common way of translating, the several viscera are made out to be of the materials just mentioned respectively, which gives the Chinese philosophy a most whimsical and absurd appearance. The five musical notes and the five of the strings of a Chinese lute, are, the former in a general work of 44 vols., the latter in an elementary work on the instrument, in 4 vols., said to correspond to gold or metal, fire, wood, earth, and water. The word rendered material in dictionaries has an abstract sense, and refers to the essential characteristic of an object, and not merely to the stuff or substance of which a thing is made. A Chinaman saw that the number five and its multiples were of very frequent occurrence in nature, as the most perfect quadrupeds have *five* fingers and *five* toes; the most perfect plants have *five*, and its replication in the parts of the blossom; and the most perfect insects have *five* joints in their foot. From thence he took the hint, and cast things that were the subject of contemplation and theory, into five categories or predicaments. Whether he was right or wrong in placing every thing under quincuncial arrangement, the inductive philosophy can teach us. At any rate, we should study and carefully collate the books which antiquity has left before we conclude that there is nothing in them but what is either absurd or useless. When he tells us that the liver gives rise to such and such thoughts, he speaks in the style of his *metaphysics*; when he couples gold with any object, he uses a technical term belonging to his *logic*. The time is coming when we shall endeavour to understand this people and their literature like wise philosophers, and labour to do them substantial good, like honest men and christians.

DR. BIGSBY
ON THE
MEDICAL RELIEF OF THE
POOR.

To the Editor of the Medical Gazette.

SIR,

I SHALL be obliged by your inserting in your valuable periodical a few facts (with reflections thereon), which I have collected for the purpose of ascertaining some important points connected with medical relief, as administered by law, in the counties of Nottingham, Leicester, and Lincoln.

Living in daily and close observation of a rural community, under the full operation of the new Poor-law, I am free to declare myself decidedly favourable to its principle, and to most of its details; though not to all, as you will perceive; and I desire only to assist the Commissioners in their high, and, upon the whole, well executed task of preserving a nation from destitution, crime, and anarchy.

The materials on which I ground my remarks were obtained at my solicitation, from the kindness of the chairman or clerks, and medical officers, of certain midland unions. I have pleasure in stating that I met with the utmost openness of communication; but I took care to seek for the *public* information alone which is printed for circulation in the quarterly abstracts of expenditure and relief.

I now present to you, in the form of two tables, some interesting particulars respecting the medical aid afforded by twelve unions, in the three counties just named, in the year 1838.

The most striking circumstance on the face of Table No. 1, as it appears to me, is the small number of sick actually attended by the medical officers of unions. It is one-nineteenth of the population in the largest proportion (Bourne) and one-sixty-first in the smallest.

This fact becomes still more conspicuous, if we look at the separate districts. I shall now present you with the results of my examination of eight.

The proportion of sick relieved by the Union to the general population,

TABLE I.

| UNIONS. | Population in 1831. | Cases. | Deaths. | Proportion of Sick relieved to Population. | Proportion of Medical to General expenditure. | Salary per Head of Population. | Remarks. |
|-------------------------------------|---------------------|--------|---------|--|---|--------------------------------|---|
| Bourn (Lincolnshire) | 17174 | 906 | .. | 1-19 | 1-20 | 24 | { Only one district given, and work-house. { Medical officers are salaried, but do not find drugs. |
| Loughborough (Leicestershire) | 17939 | 868 | 47 | 1-21 | .. | 14 | |
| Nottingham | 50680 | 2219 | .. | 1-23 | .. | .. | |
| Southwell (Nottinghamshire) | 23235 | 888 | .. | 1-26 | 1-25 | 2 | { Chester county (one district). { Grantham, Auncaster, and Bottesford districts only. |
| Newark (ditto) | 25089 | 894 | .. | 1-28 | 1-19 | 24 | |
| Altrincham | 8893 | 270 | 30 | 1-33 | .. | 14 | |
| Grantham (Lincolnshire) | 14159 | 406 | 51 | 1-35 | 1-26 | 24 | { Navenby, Metherringham districts only. |
| Sleaford (ditto) | 19832 | 548 | 64 | 1-36 | 1-33 | 24 | |
| Lincoln | 3945 | 101 | .. | 1-38 | 1-27 | 14 | |
| Retford (Nottinghamshire) | 20071 | 452 | .. | 1-44 | 1-21 | 24 | |
| Bingham (ditto) | 14773 | 291 | 21 | 1-51 | 1-18 | 24 | |
| Worksop | 16111 | 264 | .. | 1-61 | 1-32 | 2 | |

N.B.—To ask for the number of deaths was an after thought, and therefore not always obtained.

} Vide Table II.

There may be a difference of opinion; but that medical relief by law should be extended to so small a fraction of the population does seem to me to be a very undesigned and unhappy state of things. Until I had completed this little inquiry, I thought that the new system had supplied to the agricultural parts of the country most of the advantages of the well-regulated dispensaries of towns; yielding aid in sickness to those who, in fact, are only able to provide for the wants of health, and I think that they can be shown to be annually one-fifth of the community, and not very far from one-half of the whole sick.

Newark, and the country around, to the distance of eight miles, contains 25,000 inhabitants, mostly the same individuals as those composing Newark Union, and always in precisely the same employments and other outward circumstances. We can therefore look upon them as one.

Of these 25,000 (whether in the union or within the circuit mentioned does not signify), 12,500 are every year sick, incapable of labour, and require medical aid, for a longer or shorter period.

This calculation has been verified in a multitude of ways, and is now a universally acknowledged truth.

How are these sick supplied?

Of the helpless sick within our circuit, there go for *gratuitous* advice annually—

| | |
|--------------------------------|--------|
| To the physicians | 1400 * |
| To the general practitioners.. | 2200 † |
| To the Newark Dispensary .. | 660 ‡ |
| To the Union officers | 890 § |

5150

or one-fifth of the population, or nearly

* This seems a moderate statement, and is founded on an accurately kept register in one instance, and upon general information in the others. The public is little aware how extensively some provincial physicians prescribe for the poor of their respective neighbourhoods—varying for each practitioner from 300 to 1500 per annum, independent of hospital or dispensary practice.

† The number here given is under the mark. It is at the rate of two per week to each, and includes not only the spontaneously gratuitous, but defaulters also. One surgeon in this neighbourhood alone attends 600 professedly gratuitous patients every year. I wish his modesty would allow me to mention his name. Surgeons are rendered more guarded by having to give medicines together with the advice.

‡ Vide Report for 1833.

§ Vide Table I.

one-half of the whole sick; the remaining 7350 forming the portion of society which remunerates the 24 medical practitioners of the circuit.

It appears, then, from these statements (which are sufficiently accurate for practical purposes), that legal medical relief with us at present reaches little more than one-sixth of the whole *destitute sick**; nearly five-sixths being left to the charitable feelings of a profession which certainly does not luxuriate in the marrow of English opulence. Many reasons, applying alike to the patient and the public, might be advanced, why paid services should be used more extensively than at present. The gratuitous patient is seldom or never seen at home—always irregularly; the minutiae of symptoms and treatment are apt to be neglected; there is no responsibility to man. So much, in a few words, as to the patient. As much may be said on public grounds, moral, economic, and statistical. The general amount of sickness would diminish very greatly.

Newark Union is now contracted for at the low rate of 2½d. per head of the population, and the benefit to the sick is proportionately limited, although greater here than elsewhere; but new and wider doors should be opened by the union to proper objects, with a large increase to the salaries of the medical officers. Independent clubs may be called in aid, warmly encouraged among skilled workmen, with honorary subscriptions to raise the annual payments to a sufficient amount.

The Union of Newark is rather a favourable specimen of medical relief by law: that of Worksop does not accomplish half as much; it only attends to 264 sick out of 8000, who there annually require professional aid. In separate districts, the deficiency is sometimes, as we have seen, very striking.

It is not a satisfactory state of the body politic, where at least 5150 persons annually require eleemosynary aid. We cannot refuse it to them; the present sick have an implied right to, a vested interest in, the better feelings of human nature, for their immediate assistance. The remedy must be prospective, and apply to the young rather than

the old. Discipline and mercy must go together—*pari passu*.

The earnings of the agricultural labourers in the midland counties are small. In 1835, the number of subscribers to the savings'-banks in Lincolnshire was only as 1 to 59. We abound, to my knowledge, with persons living from hand to mouth, with difficulty; and who *positively cannot* (unless by a severe economy, not to be looked for) provide for a lengthened illness; such as labouring families, with four children and upwards—sickly parents with fewer children—the numerous aged—the widows—single or married persons struggling to maintain parents (and they are numerous)—servants out of place—mistresses of small schools—petty tradesmen who have been unfortunate, sometimes most innocently and unavoidably—with many other classes of individuals whom I cannot here enumerate. In these counties the journeyman shoemaker works 14 hours a day for a mere pittance, as an average through the year. Of course, health flies. It is a daily astonishment to me how labouring families exist, four-fifths of the father's earnings being spent in flour alone sometimes.

Union medical relief is rendered inoperative by many causes. Sometimes these are local and peculiar, and often easily obviated. Having first to obtain the consent of the relieving officer is a serious obstacle, as he is usually resident in a distant parish*, and is visible only at intervals. When his written order is vouchsafed, after much scrupulosity, the medical officer is yet distant some miles. The relieving officer should receive positive directions to relax in his scrutiny very considerably. Some medical officers entertain the erroneous idea that they are not bound to attend any paupers but those receiving other aid; and, in fact, in some unions relief solely medical is seldom administered.

One very prominent hindrance to the free circulation of aid to the sick (as I would have it—not the *indiscriminate*) is the magnitude of the medical divisions. These, in the midland counties, are commonly too large, as you will observe in Table No. 2, although sometimes unavoidably. It is true that the

* 890 (the number of sick attended) multiplied by 6 gives 5340, about the whole number of destitute sick.

* In practice, the overseers of parishes seldom act; they leave the decision to the paid agent.

surgeon frequently resides near the centre, but as frequently his position is not so convenient, when a great and injurious interval is placed between himself and his patients.

Sir Astley Cooper, in 1838, before the

| | |

} With variable and often great breadth.

39

In four districts, the range is eleven, twelve, and fourteen miles long respectively; and in three cases, at least, over well-peopled tracts.

When these divisions are too large, the effect is curious: it works well for the medical man on a stated salary. He is seldom called in, as might be anticipated. Promptness and frequency of attendance in this case cannot be expected; and there is little confidence in the medical adviser, a comparative stranger.

It has been repeatedly found in dispensaries and pauper practice, that a radius of three miles is the extreme limit from which any considerable number of patients will come; the applicants from beyond being few and scattered. So it is in Poor-law Unions, doubtless, as far as circumstances will permit.

The aid must be brought near to them. Wherever the poor are distant, every imaginable expedient is used to avoid sending five, seven, or ten miles for the professional man, unless he be very popular, or other relief be required.

It may, in fact, be cheaper for the pauper to employ on trust a medical man living close at hand. Somebody must lose a day's wages in journeying between the relieving and medical officers. It is frequently out of the sick person's power to send at all: whom can a poor person send long distances once and again?

I have known a journey of thirty-six miles to be taken for a bottle of medicine and a blister, or some such matter; across a tedious ferry, too. The messenger had to walk nine miles four times; the first eighteen miles for advice, and the second eighteen miles for the medicines. I mentioned this circumstance to Mr. Assistant-Commissioner Gulson, who, with many expressions of regret, put an immediate end to the possibility of its recurrence in that parish. I have read of similar instances; they cannot be unusual.

Committee of the House of Commons, most judiciously gave it as his opinion that the medical districts should not exceed five miles in diameter; but, on looking over the Table No. 2, you will perceive that the districts are in length—

I shall say, Mr. Editor, little respecting the medical salaries, excepting that they are usually hurtfully inadequate—another grand obstacle to sufficient aid to the sick poor. A close examination of Table No. 1, will afford a valuable insight into the rate of payments, the gravity of the diseases, the labour performed or unperformed, and will substitute figures for those generalities of which every one takes his own measure.

The salaries should be carefully adapted to each district per case, according to the supposed expenditure in drugs, the average number of visits to each patient, and the medium distance of each patient from the medical attendant. These are particulars easily obtained.

It is the true interest of the rate-payers of unions to afford to the poor prompt, efficient, and kindly-administered medical relief; and this can only be secured by a proper salary—a salary, be it remembered, which is not wrung from the pauper, but is paid by the real property of the country: for the *bonâ fide* poor to be attended on *terms of equal advantage* with the rich, would be the veriest economy; but it is not so. Nothing would tend more to reconcile the labouring classes to the poor-law (a high-pressure system, with not a few harsh features), than a liberal and easily accessible attendance when sick.

I fear that Mr. Assistant-Commissioner Power is but too accurate in stating (2d Annual Report, p. 267), "that the low scale of remuneration has been found an excuse for defective attendance;" although not in this vicinity, as far as I am aware.

Various complaints have been made officially, by the medical officers, of the insufficiency of their stipends, slow as they naturally are to give vent to their feelings (vide 2d Report). The dissatisfied faction in these counties, I declare emphatically, is great, and all but universal.

It must be confessed that the poor-law executive have been economising on the fears and imaginary necessities of the the profession—a procedure which, in the end, will prove a financial mistake.

I perceive that in the counties of Wilts, Sussex, and Hants, a more liberal remuneration has been granted; and that instead of the rate per head being always under 3d., as with us, it is (or has been) 4½d., 5½d., and frequently reaches 7d. per head of the population. Dr. Kay, in 1838, proposed 6d. per head before a Committee of the House of Commons.

I shall conclude these rapidly penned but well considered remarks, by stating it as my opinion that medical relief is not afforded, in rural districts, in proportion to the rightful demand; that its promptness and efficiency are much impeded by the size of the visiting ranges; and that the medical officer is discouraged by inadequate remuneration.

I know that the poor are suffering, although the various Boards of Guardians hear nothing. This arises partly from the remoteness of the labouring classes from the place of appeal, partly from their ignorance and inertness.

Remunerating clubs must be established, at a rate raised by honorary subscriptions, one-half higher than those of the Commissioners: the districts and salaries must be adjusted, and a more free distribution of medical relief (apart from any other succour) must be devised, in conformity with the opinions of Mr. Assistant-Commissioner Gulson, expressed before the Committee of the House before-mentioned, and elsewhere. These measures should be carefully digested and carried into effect by a paid medical inspector (for 12 to 24 Unions), and the respective Guardian Boards under the control of the Commissioners in London. The inspector brings professional information, the guardians local knowledge, the commissioners ensure uniformity and steady adherence to principle.

JOHN J. BIGSBY, M.D.

Newark-upon-Trent,
May 27, 1889.

EXTERNAL USE OF COLCHICUM.

To the Editor of the Medical Gazette.

SIR,

A FEW weeks ago you did me the honour of inserting in your journal a let-

ter of mine, in which I recommended the external use of colchicum in rheumatic and gouty affections. Since that time I have had many opportunities for further trial of the remedy, and I now forward you the results.

Tincture of root of colchicum used as a liniment alleviates rheumatic pains, and pains in those of a gouty constitution, in nine cases out of ten. The exceptions are very chronic cases in old people. When relief is experienced, it is perceived in from two to thirty minutes after applying the remedy. Some patients remark that a sensation of warmth, or of tingling or formication follows the application. Occasionally, small pimples have appeared. Some appear to have been not merely relieved, but cured by it. The patient, in particular, who had had severe rheumatic headache for a length of time, and which had resisted the usual remedies, was well after using the tincture for a few days.

Veneral pains.—The proportion of cases of this class relieved by it is about three in five.

Anomalous pains in various parts of the body, as of the side in young females, of the feet, &c., are generally relieved by it.

Distinctly nervous pains and headache have been sometimes relieved, sometimes not; but when relief followed, it was no more, perhaps, than would have resulted from an equal quantity of proof spirit.

Pains, the sequelæ of injuries, are aggravated so soon as the tincture is applied, but eventually relieved.

Pains connected with inflammatory action were, I think, absolutely aggravated by it.

In three cases, the specific general effects of the internal use of the tincture were observed to follow its application to the skin. In one, the tincture had been freely rubbed on the shoulder; in another, on the loins; in a third, on the abdomen. In the last case I am quite convinced the symptoms (tenesmus, mucous stools, depressed pulse, &c.) were caused by the colchicum.

Indeed, in such a case these might have been predicted, from the experience we already have of endermic medication. The ancients made very common use of purgative epithems to the abdomen and epigastrium. Aëtius gives various formulæ (Tetr. i., Sermo iii. cap. 135.) The bases of these are honey,

lead, wax, and gall; and the more active ingredients, colocynth, white heliobore, scammony, elaterium, rue, sagapenum, &c. Applied to the umbilicus and abdominal surface, they purged, excited the menses, or destroyed the life of the fetus; and, applied to the epigastrium, induced vomiting. Although these remarks are somewhat foreign to the subject matter of my letter, they may be of use in inducing practitioners to rely more generally upon endermic medication than they do. With regard to the tincture of colchicum-root, I am afraid the expense of the remedy will be an obstacle to its use. The acetous preparation will be, perhaps, cheaper, and as efficacious, and I would recommend a trial of it.—I am, sir,

Your obedient servant,

THOMAS LAYCOCK.

County Hospital, York,
May 23d, 1839.

FITS AND PARALYSIS.

To the Editor of the Medical Gazette.

SIR,

As the following case has some points of interest connected with it, I have forwarded it to your journal.

I remain, sir,

Your obedient servant,

C. J. B. ALDIS, M.D.

13, Old Burlington Street,
June 3, 1839.

Joseph Hammond, æt. 8, fair complexion, was placed under my care at the London Dispensary, April 8, 1839, for fits, which were stated to be epileptic; but as I could not clearly ascertain that he had ever bitten his tongue, I have called them convulsive fits, although, with the exception of this symptom, they were attended by all the other symptoms common to epilepsy. In addition to the fits there was paralysis of the right side; he had lost the use of the right hand, and walked with difficulty when supported by his mother. There was also a fatuous appearance about the boy, who did not seem to understand any thing which was said to him. The fits had endured five years, and varied in number from seven to twelve, or more, in twenty-four hours. Has been a patient at the Dispensary during three years. His mo-

ther is in the habit of tying him in a chair when she leaves home, in case a fit should occur while she is absent. The convulsions took place every twenty minutes on their first approach. Pulse natural; skin cool; tongue whitish; bowels open; urine free. Understanding, on inquiry, that he had been occasionally troubled with "thread worms," I ordered a powder of calomel with jalap alt. nocte.

Enema Oleosum alterno mane.—Cold sponging to the head.

April 11th.—Experienced a fit while waiting at the dispensary, and was carried to me in a drowsy condition, recovering as from an attack of epilepsy. No worms passed.

Inseratur setaceum nuchæ. Perstet.

15th.—Has about six fits in twenty-four hours.

Rep. Calom. c. Pulv. Jalap. o. n.

18th.—"Very bad." Fits no better.

R Mist. Camp. ʒss. Sp. Ammon.
Arom. mxx. ter die.

R Pil. Coloc. c. gr. v. omni nocte.

I did not see him for some days, but his mother reported to me that occasionally the fits were as bad as ever, and that the seton did not discharge freely.

May 2d.—I visited him in consequence of his mother reporting that he was very ill. He had a slight attack of fever, with sore throat, which was prevalent among the patients at that period. Tongue foul; bowels costive.

R Mist. Salin. Cathart. ʒi. ter die.

R Hydrag. Chlorid. gr. ii. hâc et crastinâ nocte.

6th.—Rep. Hydrag. Chlorid. gr. iij. hâc et crast. nocte. P.

He soon recovered from this attack, and on the 13th the fits were less in number.

20th.—Six fits. P.

27th.—Only three fits.

R Hydrag. Chlorid. gr. ij. hâc et crast. nocte. P.

June 3d.—Only one fit since the 27th, which came on last night. Can lift his right arm over the head with perfect ease, and is able to grasp my fingers firmly with the right hand; walks much better, and is quicker in his intellect. Bowels costive; great discharge from the seton.

R Pil. Chlorid. c. gr. v. alt. nocte. P.

REMARKS.—It is surprising, as the preceding case shews, for how long a period and how many convulsive attacks the constitution is enabled to sustain. The prognosis seemed most unfavourable when he was first brought to me, from the circumstance of the fits having existed so long, from their being attended with paralysis, and from the fatuous condition of the patient, which gave me little hopes of such great amendment. In cases of epilepsy accompanied by paralysis, there is frequently extensive organic disease of the brain, and medicine affords generally but slight relief. With regard to setons, I have never seen any material benefit follow their use, except in the preceding case.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abréger.”—D'ALEMBERT.

Essays on the most Important Diseases of Women. By ROBERT FERGUSON, M.D., &c. &c. Part I. *Puerperal Fever.* London, 1839. 12mo. pp. 299 and 36.

DR. FERGUSON, in his 1st chapter, divides puerperal fever into four forms: the first being the peritoneal form; the second, fever, with gastro-enteric irritation; the third, the nervous form; and the fourth, the complicated. The first form, however, is subdivided into two kinds; in one of which the pain is transient, and relieved by opiates, in the other the pain is permanent, and requires bleeding; so that, in fact, there are five forms of this fatal disease.

In the second chapter he gives the morbid anatomy of puerperal fever.

In the third, he discusses the nature of the disease, and the three following propositions embody his views:—

“1. The phenomena of puerperal fever originate in a vitiation of the fluids.

“2. The causes which are capable of vitiating the fluids are particularly rife after child-birth.

“3. The various forms of puerperal fever depend on this one cause, and may readily be deduced from it.”—P. 53.

This chapter is particularly interesting. After shewing that the symptoms produced by artificially vitiating the blood in animals, strongly resemble those

of puerperal fever, the author remarks, “that after child-birth, the womb is like an amputated stump, and that it has a reparative process to perform, which, being disturbed, permits the large gaping vessels to spread in the blood noxious secretions which they have imbibed.”—P. 80.

The fourth chapter gives the opinions of authors on the nature of puerperal fever.

In the fifth chapter, the treatment is discussed. The following are the chief points in the treatment of the peritoneal form, and are illustrated by the detail of twenty-two cases:—

“In every case of peritoneal pain, the experience of the hospital has proved that a large linseed-meal poultice, applied over the whole abdomen, affords great comfort, and not unfrequently decided and prompt relief. It should be made sufficiently thick to retain warmth for four hours, which it readily does, and sufficiently large to extend from sternum to pubes, and from side to side. It is not unfrequently tolerated, when the pressure of the bed-clothes is intolerable. I do not pretend to account for its action; but I know the fact, that it soothes pain, and generally induces copious perspiration, and a tendency to sleep. Where there are no obvious inducements for general bleeding, and nothing, on the other hand, to mark the case as eminently typhoid, 10 grs. of Dover's powder may be given as soon as the poultice is applied.

“A second visit should be made in four hours, when, if the symptoms have been alleviated, 10 grs. more of the Dover's powder, and a fresh poultice, should be prescribed. If within four hours after the second medication, the practitioner is not satisfied that the malady is yielding, he must at once resort to depletion.

“The efficacy of this plan of treatment depends on its early application. As soon as the pain has commenced, or even during the rigor which mostly precedes it, the nurse should have orders to apply the poultice, and to send for the medical attendant. Even if the plan is not successful (it having been tried, be it remembered, in cases in which the necessity of venesection is not *obviously* apparent,) the loss of six hours is not injurious; nor am I inclined, after again and again having made the experiment, to participate in the fears of those who

proscribe the early use of opiates. As long as inflammation is made up of vascular and nervous action, of the afflux of blood to a spot, and of pain, so long I do not think it irrational to act on both the elements of the malady at the same time, or in periods shortly consecutive of each other. The chief danger of the use of opium, in cases of local vascularity, consists in the diminution it causes of the secretions. But with regard to the malady in question, this may be obviated by using the Dover's powder, and combining it with an aperient, especially the mercurial preparations. In this way, while pain is soothed, the skin, liver, and bowels, are acted on.

"Where the malady is not immediately ameliorated or arrested, it runs into one or other of the various forms I have described, and requires a mixed treatment. On inspecting my tables, it will be seen that forty cases, or one-fifth, were treated without any bleeding or leeching, or without any bleeding or leeching, or without any attempt to induce the constitutional effects of mercury, and of these two only died.

"I might cite authorities in favour of the use of opiates in puerperal fevers, but I shall content myself with instancing Chaussier, and quoting the fifth case of Gordon of Aberdeen, who, despairing of cure, gave to a patient, writhing with the agony of a swollen and painful abdomen, a full opiate as a palliative; it proved, to his astonishment, a cure. This example is the more valuable, as it comes from one whose sole axiom, in treating this malady, was a full bleeding, followed by a full purge."—P. 114.

"I have attempted to arrange the above cases so that the student may see—1st, That the chief intensity of the malady is expended on the peritoneum. 2d, That there is every variety in grade of that intensity. 3d, That some of these are best relieved by acting on the nervous element of inflammation, while others require in addition depletion. If we take abdominal pain as the point on which the attention is fixed, we shall find that it is accompanied by two very different states of constitution; one in which little or no depletion is borne—another, in which relief is obtained only by very large evacuations of blood; between these two points there is every

imaginable grade realised in practice, and in no malady are a cautious boldness, and a sagacious adaptation of remedy to constitutional power, more imperatively demanded than in the treatment of puerperal fever. No rule can be laid down which will suit every case.

"The absolute variation in the intensity of the peritoneal attack may be inferred as really existing, from what is seen in the action of the malady on parts exposed to the eye. Thus, in what I have termed local deposit, occurring in the limbs, we can see every grade of attack on organic texture. In one case there is mere flushing, in another pricking pain, in a third congestion with black suffusion, in a fourth various effusions, and in a fifth gangrene. What is here produced externally and visibly corresponds, I believe, to what takes place internally and secretly in the abdominal cavity, or in the parenchyma of the liver, the spleen, or the lung. It is here that Dr. Gooch's profound remark finds its application, namely, that the power of the constitution is often only made known by the effect of the remedy. The practitioner will be egregiously deceived if he relies on any single symptom as an infallible guide for depletion, for example:—The majority of cases of puerperal fever do not fall into two classes, so well characterised, that the one shall require copious bleeding, the other none; but in the same hospital, and in the same epidemic, three or four patients, consecutively, will be cured by copious blood-letting, yet the fifth and sixth, apparently as capable of bearing it, will faint after the abstraction of a few ounces. It was the insufficiency of symptoms as the sole guide, which made Gordon and Campbell assert we ought not to depend on them, but bleed in every case of puerperal fever; since, even in those apparently typhoid, the remedy will remove the oppression of the system, and unveil the true nature of the malady. This rash and exclusive practice, however, is now regarded as untenable in experience. John Hunter also acknowledged the insufficiency of symptoms as a guide to depletion in all cases, and recommended what he termed a 'tentative bleeding.' A small quantity of blood was taken, its effects on the constitution noticed, and the indications afforded by its coagulation,

aspect, &c. noted; and from these collective signs did this great man determine as to further depletory measures.

"The following is the sum of my own experience of bleeding as a remedy in puerperal fever:—Of all the means we possess of arresting this malady, I believe bleeding general or topical to be by far the most extensively applicable. The cases in which it is not so are exceptions to the rule. Mercury, turpentine, emetics, opiates, sudorifics, &c., have a more limited range of utility than abstraction of blood. But while I admit this, I am equally certain that *large* bleeding has not been borne in this malady, generally speaking, during the last twelve years.

"Those who have borne it best and required it most were—1. Those who were originally vigorous, and in whom no chronic ailment of the intestinal canal or lungs previously existed. 2. Those in whom the fever was accompanied by a general turgor of the frame, their aspect being that of a person who has been flushed by running, and forming a marked contrast with the pinched, shrivelled, and stricken looks of those labouring under the typhoid form of the malady. 3. Those in whom the disease seemed to be limited to one organ.

"It may be asserted, with more hesitation, however, that they who are confined out of an hospital exhibit greater reactive powers than those who are confined in one.

"The pulse, as Gordon has remarked, is very deceptive; and the cases I have given shew that painfulness is no sufficient criterion of the necessity of depletion.

"Besides these general indications, epidemic puerperal fever has, invariably, the character common to the ordinary fevers raging with it: if the latter require depletions, the presumption is, that the former will also."—P. 150.

Passing over the treatment of the gastro-enteric variety, we come to that of the ataxic forms, which appears to consist chiefly of opium, quinine, stimulants, and aperients. The following observations on the nervous variety of puerperal fever add elegance to truth:—

"Of all the forms of this disease, this is one of which the least satisfactory account can be given. It has long been known to physiologists, that disturbance of the functions will kill as

rapidly as alteration of structure; and that the wheels of the living machine will as surely cease to move, if their motions be not in harmonious adaptation, as when the matter of which they are framed gives way. But the mode of death, from the first point of hindrance up to the last, is a great mystery, to be fathomed by him only who shall reveal how that most marvellous portion of our frames, the nervous system, connects man with two worlds, the material and the invisible.—P. 175.

"It is the characteristic of this age to attempt to raise the veil which hides this knowledge from us; but as yet it has merely ascertained a few, a very few of the *organs* even, in which some of the thousand powers inherent in the nerves are situated, and that too with hesitation and doubt. When the whole of the elements of nervous function shall have been discovered—when the organs in which they reside shall have been detected—their combination and mutual action forming the complex phenomena of life will still remain to be interpreted. No wonder, then, that our knowledge of nervous malady should be slight and superficial."—P. 175.

Dr. Ferguson speaks of the treatment of the fourth or complicated form in a tone of despair; for he observes, "it is only in its slighter grades that this form is curable; where it is the leading characteristic of an epidemic, the vast majority will die."—P. 199.

Our author discusses in turn, the principal remedies which have been tried in this variety of the disease—namely, emetics, purgatives, mercurials, and Dr. Stevens's mixture. His observations are very instructive, but we cannot afford to quote any of them. A number of cases are then given, illustrating the morbid anatomy of this fatal form of puerperal fever. The appendix contains an abstract of Mr. Gulliver's paper on Suppuration; a letter from Dr. Copland, on the Treatment of Puerperal Fever; a letter from Dr. Watson, on the use of Opium in certain Inflammatory Diseases; and several tables which are most useful contributions towards the statistical history of puerperal fever. In the period from March 1827 to April 1838, there were 205 cases of the disease, and 68 deaths from it, in the Westminster Lying-in Hospital.

The volume is concluded by a lecture

on the Method of Induction, and its results in Medical Science, delivered at King's College in 1836.

We will terminate this long review with two remarks.

It is but too clear, as we lately remarked in our leading article, that lying-in hospitals are entirely adverse to the object for which they were chiefly instituted, that of saving human life. It is equally manifest, that they might be improved if a sound practitioner resided in the house, capable of acting in emergencies with that confidence which knowledge alone inspires; for the physicians commonly live at some distance, and irrecoverable time is lost before they arrive. "I have not had many opportunities of exhibiting emetics," says our author, "chiefly because I have not seen the patient till after the favourable moment, which is at the commencement of the malady, has passed."—(P. 205.)

Dr. Ferguson's work shows great talent as well as industry, and cannot be read without profit either by practitioners or students.

MEDICAL GAZETTE.

Saturday, June 8, 1839.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

PRACTITIONERS AT HOME AND ABROAD.

We believe there is no profession or trade in which there is so vast a distance in regard to worldly prosperity and social estimation, between the highest and the lowest of its members, as in medicine. We took occasion to notice, last week, a fact which may mark the lowest descent that the profession has yet made; one of its members actually advertizing for a situation in which he "would not object to perform the duties of a valet;" and yet at the opposite end of the scale there are as many as ever, who not only keep their own valets, but live in a style of costly splendour, and in the enjoyment of every luxury that wealth can purchase.

An observing foreigner (one of the many who are now arriving every day) would be much puzzled to account for such an apparent anomaly, and still more to arrive at any definite or just conclusion on the state of the profession in this country as compared with its condition in his own. Yet this is the kind of evidence on which travellers so generally form their hasty conclusions, and on which, in regard to our profession, foreigners acquire the most ludicrous ideas either of its magnificence or of its degradation. They look only at the extremities of the scale; and have entirely neglected the intermediate, but far more numerous and important class, by which the real average of the mental and social condition must be estimated.

For one nation to challenge another to produce a professional man of equal excellence with any one of its own, and from the individual merits of each to decide upon the condition of the mass (as is so generally done) is most absurd: a man might as well describe the general stature of Irishmen by measuring the skeleton of O'Byrne. An estimate of the talents of the leading men in any profession can afford no evidence of the present general condition of its members, though it may give some idea of their future improvement or deterioration; it requires some time for "inferior minds, who borrow their behaviour from the great," to "grow great by their example"; and the general improvement of intellect by the influence of a few choice minds, though it may be as sure, is not more rapid than the physical improvement of a race by the introduction of a few vigorous individuals of a better stock. While she had Harvey and Hunter, for example, England might safely have thrown down the gauntlet to the world to produce such intellect employed in medicine; yet the general intellectual standard of the profession was far lower

at either of these periods than it is now.

It is difficult to arrive at any fair estimate of the condition of the mass of our profession in another country. In Paris, for example, one rarely by any chance sees or hears of a practitioner of the crowd; the names of their hospital physicians and surgeons, and the lecturers of the *école* and college, become familiar before one has learnt the name of a single private practitioner; yet there are, of course, vast numbers whose professional reputation scarcely extends beyond their own circle, in whose care are the lives of the majority of the population, and who therefore constitute that which to the present race is by far the most important class. Their condition is a matter, therefore, of the gravest interest and importance to the public; and, as we have often urged, all schemes of education (due regard being had to prevent the scientific study of medicine from retrograding) should have for their main object the insurance of the highest possible degree of excellence for the greatest number, or what we would call the mass of the profession. By attaining this, the greatest amount of life will be saved, and the greatest amount of pain alleviated, and so medicine will have most efficiently supplied its office, and given the best boon for its remuneration.

In regard to the pecuniary and social condition of the practitioners in this and other countries, however different they may be absolutely, they are about equal when viewed relatively to the circumstances in which each is placed. The Parisian physician may be content with five francs for a service for which the English physician, though perhaps of inferior eminence and talent, would receive his guinea, and all other classes of practitioners may be proportionately remunerated; but the seemingly great disparity is soon com-

pensated by the difference of expense at which the two are obliged to live. If fees are low, so are rents, and taxes, and provisions; and if a man is paid well, he is expected to make a good appearance. By this compensating arrangement, practitioners of both countries probably live up to their income, and occupy about the same general station in society. This, indeed, is but natural; the public are no judges of professional merit, and in the present day, with some brilliant exceptions, give station to practitioners rather in accordance with their birth, parentage, and education, than with any reference to their power of curing disorders. Indeed, it is worthy of observation that medical practitioners have rather fallen in the public respect, while their real knowledge has been increasing. The practitioner, however able, of the present day, for example, is far less estimated than the practitioner of centuries ago; and the reason is clear; a large portion of the public, who were then at an immeasurable distance from him, are now on a level with him in all branches of general information, and being unable to appreciate the value or the difficulty of attaining a sound professional knowledge, regard themselves as in all respects his equal. It is unnecessary to adduce stronger evidence in support of any system which would insure a better (we do not mean a more widely and superficially extended) education for students than this—that the profession is now considerably lower in its social relations than it formerly was, although it has been rapidly rising in its general standard of scientific knowledge.

We know nothing that is more likely to afford a good criterion of the intellectual condition of the mass of general practitioners than the contents of the periodical records of practical medicine,

as distinguished from those more generally quoted, which are devoted to the sciences collateral to medicine. The latter, however well they may shew the progress of the dominant pursuit, and the general tendency of the minds of the scientifically-working part of the profession, have no relation to the majority, who neither write nor read them. Müller's *Archiv* for example, clearly enough shews the widely extended taste for physiology in Germany, but affords no idea of the practical knowledge of those under whose care the sick fall. If we judged of them by the writings of the contributors to this excellent and scientific work, we should imagine the practitioners of Germany to be, by comparison with those of France or England, scarcely fit to undertake the management of the simplest disease, so complete is the absence of any knowledge of the useful applications of scientific medicine, and so vague and incorrect the pathological illustrations of structural anatomy and physiology.

For a fair comparison it is necessary to examine the records of practical medicine—those, for example, which are extracted from all sources, and placed in Schmidt's *Jahrbucher*, or those in Hufeland and Osann's *Journal*—those of the *Gazette Médicale*, the *Gazette des Hôpitaux* (*ci-devant Lancette Française*) or the *Archives générales de Médecine*—those of the *Annali Universali di Medicina*—and those of our own weekly and monthly publications. Taking these as a guide, it will be readily granted that the general tone of the English communications presents a more earnest attention to utility, and that the actual amount of practical knowledge which they evince is several degrees higher than that which seems to be possessed by the continental contributors.

The general tone of the English writings of this class appears to be the offering of useful, though some-

times illogical, deductions from actual practice; the manner in which the practitioner may best acquit himself, and obtain the most reputation in a given class of cases, is told, and a mutual benefit is thus constantly afforded; the applicable knowledge of each of the mass is daily increased, and the public are proportionally and immediately benefited.

In the corresponding writings of Frenchmen, one is at once struck with the idea that the papers are composed more for the sake of insuring the author a reputation among his *confrères*, than for the benefit of the public. The treatment of the disease is often omitted, very generally slurred over, and never so much or so carefully considered as its pathology. To judge them by writings of this class, the French would appear to be most inefficient and unsuccessful practitioners: operations, deaths, and post-mortem examinations, occupy five pages out of six, while the treatment towards a cure or an alleviation of suffering, fills, perhaps, only a few lines. But the difficulties of studying pathology (the present dominant French science) in private practice, prevent the great majority of practitioners from writing at all; they are, therefore, on the average, rather below the grade which would be estimated from the periodicals, for they receive their practical knowledge from those who have themselves too much neglected it in the pursuit of pathology; and the study of practice being unfashionable and ill rewarded, there is little inducement to exert themselves for their own improvement or for the present good of the public.

In Germany, the preponderating influence of physiology, and the attraction which it affords to all those of leading intellect, has led to a still lower average of practical knowledge among those in whose skill the public is especially interested. We see every day, communi-

ications to their periodicals of practical medicine, which would scarcely do credit to our nurses: the most crude ideas of the influence of remedies—the exaltation of some of the most inefficient to the rank of the most useful—the praise of many which experience has elsewhere long proved to be inert—and confused and disorderly formulae—afford a fair idea of what a medical periodical would have been in England two centuries ago. We speak only of the writings of the mass of actual practitioners, more of whom write in Germany than in any other country. Their physiologists now form a school which is, beyond comparison, the most intellectual and successful that ever existed; but the present public pay for this eminence, of which the unborn of far distant years will reap the sure benefits.

But what is the fair inference that may be drawn from these several cases, as to the best mode in which medicine may be taught for the benefit of the public? There can be no doubt that the philosophical study of it will most certainly ensure its improvement, and soonest obtain its perfection. Common practical experience is insufficient for this: nearly all that has been done profitably in the last 2000 years is the work of the scientific minority: yet it is hard and unfair that the present generation should suffer, while their medical men are in pursuit of advantages for their successors. A union of the two systems seems far better than either singly. All should be taught to practise, and to practise well; and scientific progress may be left to those whose talents, independent means, or taste, lead them to it. Science has never suffered by being left to a few; its pleasures are wages sufficient to ensure, if not to repay, an ample supply of labourers; but the medical sciences (as distinguished from the knowledge of its simple practice) have

not yet a utility proportionate to the difficulty of attaining them, and are mischievous when generally pursued with the sacrifice of knowledge more immediately applicable to practice.

DR. THOMAS DAVIES.

WE regret much to announce the death of this gentleman, which took place at his residence in Broad Street, on Saturday, the 1st instant.

Dr. Davies was assistant-physician to the London Hospital, and one of the physicians to an Institution in the City for Diseases of the Lungs. He had paid much attention to the morbid states of the thoracic viscera, particularly with reference to the physical signs by which they are indicated. Some valuable lectures by the deceased, on these subjects, appeared in our 15th volume, which were afterwards given to the public in a separate form.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

May 28, 1839.

THE PRESIDENT IN THE CHAIR.

On a peculiar Form of Congenital Tumor of the Neck. By CÆSAR HAWKINS, Esq.
Surgeon to St. George's Hospital.

THE author's intention in the present communication is not to refer to the tumors met with in such variety in new-born infants, which are liable to immediate or future increase, and are composed, for the most part, of a single cyst, with various contents; he, on the contrary, restricts himself to the consideration of a peculiar form of congenital tumor, which is composed of many cysts joined together, in which the proportion of organized matter is so considerable as to give a more solid character to the tumor, and make it deserve the character of *cystic tumor* as much as the apparently analogous cases of *cystic sarcoma* occasionally found in the breast, testis, or ovary of adults.

The author having met with seven such tumors in the necks of young children, was led to hope that he may be enabled to throw some light upon their diagnosis, which may be acceptable to the society. He accordingly relates the details of several of them, one of which was treated with complete success by the method pointed out by the author; and some others were in a state of progressive amendment when lost sight of by him. The treatment is described by the author

as follows:—1st. The cysts may be emptied from time to time by a grooved needle, so as to leave no scar whatever, or by a lancet, when situated in the mouth. 2dly. Pressure may be employed, especially after the evacuation of the fluid in some situations, as in front of the ear, although, of course, this means is generally inapplicable, on account of its obvious interference with respiration, mastication, and deglutition. 3dly. Stimulant applications may be constantly employed of such a strength as to excite moderate inflammation, but stopping short of supuration to avoid deformity. The applications employed by the author have been, the ointment of hydriodate of potassa, rubbed in by the hand; a solution of a drachm of iodine and 2 scruples of hydriodate of potassa in an ounce of water, painted over the tumor. One of the patients, a child, 11 weeks old, sent to the author by Dr. Willis, having died, an opportunity was afforded for a minute examination of the tumor, of which the author relates the circumstances in detail.

A paper was next read by John Webster, M.D., consulting physician to the St. George's and St. James's Dispensary, detailing the particulars of some cases of measles occurring more than once in the same individuals.

A remarkable case was then narrated of dry gangrene occurring in a child of three years and seven months old, by Samuel Solly, F.R.S., lecturer on anatomy at St. Thomas's Hospital.

William Chandler, the subject of the disease in question, is the son of a barge-man, and it is probable, from the high wages earned by his father, is better nourished than the greater number of the children of the poor. He was under the immediate superintendence of Mr. Bayley, of Odiham, who was unable to discover any thing in his diet to explain the occurrence of the remarkable form of disease under which he laboured.

The author visited the patient in company with Mr. Bury, of Farnham, on the 29th of January last, at which time three of his limbs—the left leg and both arms—were in an advanced state of destruction by dry gangrene. Three days before his first visit the right forearm had been amputated by nature at the elbow-joint, but the slough had extended above the joint, where a second attempt at amputation was in progress. The foot of the left leg was completely removed just above the ankle-joint, between the epiphyses and the shafts of the tibia and fibula, leaving the extremities of the bones exposed. On the right foot the phalanges of the second and third toes had been removed.

The author learned from the mother of the child that the disease had begun in the month of August last, both his feet becoming of a purple colour. Sloughing had commenced in September on the right leg. These sloughs separated, and the wound healed in a month; that on the left leg never healed, but gradually opened, and a line of demarcation being set up, amputation gradually took place, and the limb was entirely removed on the 30th December. It is impossible to convey, in the brief space of an abstract, an adequate idea of the appearance of the several limbs, whose condition, while the disease was in progress, and after nature had wrought the cure, is shewn in two spirited sketches which accompanied the paper.

The stump of the left arm promised to be rather conical, but those of the leg and arm will be fleshy and round, equally so with many stumps resulting from artificial amputation.

The last meeting for the present session will be held on Tuesday next, the 11th instant.

WOUND OF KNEE-JOINT.

To the Editor of the Medical Gazette.

SIR,

THE following case is interesting in many points of view; but particularly, first, as to the absence of constitutional disturbance in so severe an injury to the knee-joint; and secondly, as shewing the injudicious haste with which amputation is often resorted to in accidents of this nature. You will much oblige me by its insertion in the next number of the MEDICAL GAZETTE.—I am, sir,

Your most obedient servant,

J. B. SAMUEL,
House-Surgeon,

Newark Dispensary,
June 1, 1839.

CASE.—Thomas Tebb, maltster, æt. 28, was admitted a patient of the Newark Dispensary on the 9th of July, 1838, in consequence of having sustained an injury of the knee, from falling on the edge of a scythe, being at the time under the influence of liquor. On examination, there was found to be a semicircular wound, six inches in extent, passing round under the knee-cap, dividing the ligamentum patellæ, and thus rendering the joint completely exposed. The synovia had escaped, and the wound was filled with dirt. A deep wound had also been made in the muscular substance of the thigh by the point of

the scythe. The parts having been cleaned, the edges were brought together, and retained by four sutures. An opiate was ordered, and spirit lotion to the part.

July 10th, 5 A.M.—Had passed a tolerable night. No constitutional disturbance.

10 P.M.—No unfavourable symptoms had yet appeared; pulse 82. Bowels not having been opened, ordered—

℞ Pil. Hydrarg. gr. iij. Sap. c. Opio,
gr. v. F. Pil. ij. hor. som. sum.

℞ Pulv. Jalapæ, ʒj. Zingib. gr. v.
F. Pulv. cras. mane sum.

11th.—Had passed a good night. Skin cool; tongue moist; pulse 72; bowels not yet acted.

10 P.M.—Bowels freely opened; pulse 76.

Rep. Pilulæ.

12th.—Going on well. Pulse 78; bowels confined.

Rep. Pulv. Aper.

13th.—Passed tolerable night; bowels open. Slight discharge from wound, but complained of no pain. Pulse 76.

Rep. Pilulæ.

14th and 15th.—Going on well.

16th.—Some of the dressings, and one of the sutures, were this day removed: union had taken place to a considerable extent; very slight healthy puriform discharge; synovia flowed in large quantity, and had become less albuminous than natural.

Lotion and opiate to be discontinued.

17th.—Removed all the dressings and sutures; union had taken place throughout almost the whole extent. On inner side of knee a small orifice, through which the synovia flowed copiously. In consequence of restlessness on previous night, ordered—

Acet. Morphiae, gr. ss. hor. som. sum.

18th.—Going on well; allowed mutton chop and four ounces of porter.

Rep. Pil.

19th, 20th, 21st.—Going on well.

22d.—Wound looking exceedingly well; healthy granulations springing up.

Discontinue opiate.

24th.—Doing well. Ordered—

Quinine mixture, and pint of porter daily.

26th.—Discharge of synovia considerably lessened.

August.—Slow and gradual improvement. Allowed two pints of porter daily.

September.—The opening on inner side

of knee has completely closed, though the surface remains in a state of ulceration. The patient gained strength and flesh rapidly this month. All medicines discontinued.

October.—A very slight sore, requiring to be dressed once a week, remains. Discharged Nov. 8th, perfectly cured.

The joint, of course, remains ankylosed. From division of the legamentum patellæ, the patella is drawn up by the rectus muscle above its natural situation; and from the same cause he is unable to bring the heel nearer than an inch and a half from the ground. With this exception he is as well as before the accident, and is now pursuing his usual employment.

OPERATION FOR WRY-NECK.

To the Editor of the Medical Gazette.

SIR,

THE axiom, "There is nothing new under the sun," scarcely needs confirmation, and yet I cannot resist the temptation to furnish you with a fresh proof of its legitimacy. Take one of the few passages worth recording in "Ward's Diary," the whole of which was written between the years 1648 and 1679. Is it not truly lamentable to be thus forced to trace back the brilliant operations of Dr. Stromeyer to a mountebank of the 17th century? But are not most brilliant discoveries subject to similar penalties? *Voici le fait!* In offering which to your attention, I beg to subscribe myself, sir,

Your most obedient servant,

ANTIQUARIUS.

"The mountebank that cutt wry necks, cutt three tendons in one child's neck, and hee did it thus: first by making a small orifice with his lancet, and lifting up the tendon for fear of the jugular vein—then by putting in his incision knife and cutting them upwards; they give a great snapp when cut. The orifice of his wounds are small, and scarce any blood follows. Some are wry neckt from the womb; they only lay a melilot plaister to heal the wound; the plaister must bee a fresh one every day. As for the symptoms of this cutting, they are only these: that about a day or two after, the child will bee sickish, some humour falling on the stomach of itt, as the mountebank says. When hee hath cutt itt, hee bends the child's neck the other way, and puts on a capp and a fillet tied to the capp, and so ties it under the armpitts, and so by constant bending the head that way, itt becomes straight and upe right."—*Ward's Diary*, pp. 273-4.

PRIZE QUESTIONS PROPOSED BY THE SOCIÉTÉ DE PHARMACIE.

I. *Polygonum tinctorium*.—In April 1840, the society will give a prize of 1,500 francs to the candidate who shall send in the best answers to the following questions:—

1. To determine what are the substances which enter into the composition of the *Polygonum tinctorium*.

2. To determine the exact proportion of indigotine contained in this vegetable, and to ascertain in what state it is found there.

3. To point out a method of extracting the colouring matter, capable of being used with advantage, and of furnishing a product comparable to the best kinds of indigo found in commerce.

II. *Adulterations of Copaiba*.—The therapeutic importance of copaiba has long pointed out the necessity of affording druggists a method of recognizing its adulterations; but in spite of every attempt, no characters have yet been discovered peculiar to the balm of copaiba, and therefore capable of distinctly showing the presence of foreign substances fraudulently introduced into it. Magnesia, which has been shewn by the experiments of M. Mialhe to possess, in small doses, the property of solidifying the balm of copaiba, seemed at first a certain and convenient test; but it was soon ascertained that some samples of copaiba, of authentic origin and incontestible purity, did not possess this property, which assuredly belongs to others. On the other hand, an equally important observation has been made, that certain substances, particularly the turpentine of the maritime pine (*pin maritime*) may be added to copaiba, and even in considerable quantities, without destroying its property of being solidified by magnesia.

Such being the state of things, the Pharmaceutical Society hopes to do the art some service in drawing the attention of chemists and druggists to this subject. It has consequently thought it right to propose the following prize questions:—

1. To determine what kinds of copaiba are solidifiable by magnesia.

2. Does this property depend on the age or any other spontaneous alteration of the balm, or is it inherent in certain varieties, according to the botanical species which furnishes them?

3. How can the presence of the turpentine of the maritime pine, or of any other substance having the power of being solidified by magnesia, be recognized in the balm of copaiba?

A gold medal of the value of 300 francs will be given to the author of the best memoir on these questions.

III. *Pectine and Pectic Acid*.—The Society again proposes the prize offered in 1836 upon the following question:—

"It is required to point out the phenomena which accompany the transformation of pectine into pectic acid, and the differences which exist between these two substances?"

The reasons which induce the society to propose this question afresh are sufficiently set forth in the programme of 1836 (see the *Journal de Pharmacie*, tome xxii. page 718). The society will merely remark, that since that time the question has made general progress through the labours of M. Regnault, and his analysis of pectic acid (see the *Journal de Pharmacie*, tome xxiv). The candidates will find an important element towards the solution of the question in his essay. The society also thinks it right to recommend to their attention the microscopic observations of M. Cagniard-Latour on the same subject. In fact, these observations throw an entirely new light on the phenomena of vinous fermentation, which is connected, in the fermentation of acid sugars, with the disappearance of the pectine, and the formation of the pectic acid.

A gold medal worth 1000 francs will be given to the memoir which shall fulfil the conditions of the programme.

IV. *Immediate principles of Digitalis purpurea*.—Lastly, for the reasons given in preceding programmes, to which it refers candidates, the society again proposes the following question:—

"Does there exist in the purple foxglove one or more immediate principles to which the medical properties of the plant may be attributed?"

A gold medal worth 500 francs is devoted to the solution of this question.

The memoirs, which must be written in Latin or French, are to be addressed to M. le Secrétaire général de la Société, rue de l'Arbalète, 13; with a motto, and the name of the author sealed up, before the 1st of December 1839.—*Journal de Pharmacie*, and *Revue Médicale*, April 1839.

ANTI-NEURALGIC MIXTURE

OF DR. LIEGARD, OF CAEN.

℞ Aquæ Lactucæ,
Aquæ Lauro-cerasi, aa. ʒij*.
Extr. Lactucæ†, gr. xv.

* As the French *gros* contains 72 grains, it would be more exact to translate this quantity by gr. cxlii.

† In the original it is *Extrait de Thridace*; but as *thridace* is itself an extract of lettuce, this is probably an error.

Extr. Belladonnæ, gr. vj.
Extr. Hyoscyami, gr. viij.
Extr. Stramonii, gr. x.

Syr. Valerianæ, ʒj.

The potion is to be taken in the dose of a teaspoonful once, twice, or thrice a day; the dose of the mixture is from five to six drops in sugar and water, when taken internally, and a teaspoonful when used externally. These two methods of administration are employed at the same time.—*Gazette des Hôpitaux*, April 16, 1839.

RIOTS AT PARIS ON THE 12TH MAY.

THE *Gazette Médicale* says, that the number of wounded and dead soldiers in the hospitals has been incorrectly given in the daily papers, and that the following is a correct list, as far as regards the *militaires municipaux, ligne, ou autres*; including, therefore, of course, national guards and gendarmes:—

At the *Val-de-Grâce* 10

Of whom two were brought in dead; the rest are not seriously wounded, with the exception of two, one of whom has a penetrating wound of the chest, and the other has had his arm amputated.

At the *Hôtel-Dieu* 21

Of whom six are dead; of the other sixteen, perhaps a third has been lost.

At *St. Louis* 10

Of whom one is dead; among the other nine there is a case of amputation at the shoulder-joint.

41

There is no soldier in any other hospital; so that the number of wounded is only 41, of whom 9 are dead.

ON THE

CHEMICAL HISTORY, PATHOLOGY, AND
MEDICAL TREATMENT

OF

CALCULUS,

AND THE VARIOUS DISORDERS OF THE

URINARY SYSTEM.

By DR. VENABLES.

In women.—In consequence of the peculiarity of structure in the urinary organs, females are not only less liable to calculous accretions, but even when formed they produce symptoms somewhat different from those in men. From the comparative shortness of the urethra in women, a calculus, whether it have passed from the kidney into the bladder, or have originally formed in this last, is much more easily evacuated before it attains to any great size. Neither is there that excessive pain either on voiding or attempting to void the urine, described as attending the 'same' efforts in the male. When they suffer from vesical calculi, they experience a sense of itching about the genitals, and hence are often irresistibly compelled to scratch them. In such cases, too, they frequently feel the calculus, if it should happen to touch the neck of the bladder*. But not only is the calculus more readily voided, but the female urethra admits of such easy and great distension, that these means of extracting calculi will be mostly adopted, so as to pre-

vent them attaining any great size in women.

Causes and pathology of calculi.—A division of the causes of calculi, founded upon their operation, immediate and remote, would be extremely difficult; nor, indeed, would it be possible always to preserve their distinct operation. The tendency to various deposits in the urine, seems to be connected with certain conditions of the system not always specifically determinable. In many, the predisposition seems to be hereditary: in some it seems associated with gout, which we know to be an hereditary disease; and lastly, a calculous diathesis seems not unfrequently to be acquired. Again, we find that there are several species of urinary deposits; and upon dissection of calculi, it has been observed that there are but very few instances of calculi consisting of purely one species only. We find that they consist of mixtures of one or more of the principles, either intimately and confusedly intermixed, or that one or more of these varieties alternate with each other, shewing that at different periods the urine deposits different kinds of sediment. The table annexed, copied from Dr. Prout's work on the Urinary Organs, shews the composition of calculi found in the collections of different localities, and therefore may be considered a kind of statistical view of the different localities.

In this table it will be seen that the first column gives the general character; the second the particular species; the next columns point out the collections, and consequently the localities, while the next presents us with a general summary.

When we compare the results furnished by this table, we find that the calculi comprehended under the head of lithic acid—that is, all those in which this principle predominates—form somewhat more than one-third of the whole number; and this proportion holds

* *Feminae vero oras naturalium suorum manibus admotis scabere crebro coguntur: nonnunquam, si digitum admoverunt, ubi vesicæ cervicem is urget, calculum sentiunt.*—*Cels. lib. ii. cap. 7.*

TABLE OF THE COMPOSITION OF CALCULI

In different Collections, determined by Brande, Marcet, Henry, and Smith, from Dr. Prout's work on the Urinary Organs.

throughout nearly all the individual collections, with the sole exception of that at Guy's, in which it amounts to about a fourth of the whole. Lithic acid is by far the most common nucleus upon which calculous matter is deposited: it therefore becomes a legitimate inference, that nearly two-thirds of the entire number of calculi originate from lithic acid; for if a nucleus of this principle had not been furnished, and remained in the bladder, no calculous deposition would have taken place; consequently, two out of three of those who now suffer from stone would have enjoyed a complete immunity. This is a fact of considerable importance, and deserves serious consideration.

Now lithic acid separates from the urine under two modes—the *amorphous* and the *crystallized* form. It has been already shewn, that when it assumes the amorphous form, it is usually combined with ammonia, and appears as a lithate of ammonia; but when it assumes the crystallized character, it for the most part consists of lithic acid, nearly pure. “Now this distinction,” says Prout, “appears to me to hold good with respect to lithic acid calculi, some being composed of amorphous sediments and some of the crystallized, but in by far the greater number of a mixture of the two.” . . . “Every one,” continues the same respectable authority, “I repeat, must have remarked this circumstance; and the natural inference appears to be, that the red crystallized calculus is composed of the red crystallized gravel, and the earthy amorphous one of the amorphous sediments: and this inference seems to be justified by experiment; the crystallized calculus being, according to my experiments, composed of nearly pure lithic acid, and the amorphous one of lithic acid, more or less of ammonia, generally a little of the phosphates, and sometimes a small portion of the oxalate of lime. The lighter the colour, the greater in general the proportion of the lithate of ammonia and the phosphates*.” Here are calculi in which you may see these doctrines fully confirmed, and no doubt the principle just now stated generally obtains.

Of the varieties of lithic calculi, the amorphous appears to be the most frequent, and the crystallized lithic acid comparatively much more rare, which appears to obtain only in the largest descriptions, but a mixture of the two is the most common. Lithate of ammonia is by far the most rare, and seems to be confined rather to children or those under the age of puberty.

From the same table, if we examine the general totals, we shall find that oxalate of lime, or the mulberry species, constitutes somewhat less than one-seventh of the whole of the calculi. But we do not find that this ratio prevails throughout the different collections, but that the proportions in this respect differ very much from each other. Mr. Brande found only six mulberry out of one hundred and fifty which he examined, which is very nearly in the ratio of 1:26; and even of these, Mr. Brande asserts that the purest contained as much as 35 per cent. of foreign matter. At Guy's Hospital, Dr. Marcet found twenty-two out of eighty-seven calculi to consist of oxalate of lime, which is nearly one-fourth of the whole; and in the Norwich collection, according to the same authority, out of one hundred and eighty-seven, forty-one were oxalate of lime—a proportion nearly coinciding, though somewhat short of that at Guy's. At Manchester, only eleven out of one hundred and eighty-seven were composed of oxalate of lime, which is exactly in the ratio of 1:17; and at Bristol, according to Mr. Smith, of the two hundred and eighteen calculi which he examined, he found only thirty-three to consist of oxalate of lime, which is exactly as 1:6. But when we come to compare all the calculi containing this substance, nearly one-half would be found to be composed in some degree of oxalate of lime, and therefore it may be inferred that this species prevails to a great extent in the district of Bristol. The rarity of oxalate of lime in the Hunterian collection examined by Mr. Brande, compared with the frequency of the same in the Bristol district, presents a subject for interesting inquiry.

The rarity of cystic oxide affords no data upon which to estimate the ratio of its prevalence. This substance, however, has been more frequently met with since; but still there is no inference to be drawn in relation to our present investigation.

The phosphates generally seem to constitute about a fourth of the whole. Of the eight hundred and twenty-three calculi examined in the foregoing table, two hundred and two consisted of the phosphates generally; and ninety-one of these are constituted of the fusible or mixed phosphates, forming about one-eighth. But the inferences deduced cannot be depended on as correct, for many may have contained a lithic nucleus. Many of the calculi were not sawn through, and therefore the external layer only could be examined. This was the case particularly in the Norwich collection, as Marcet thus expresses himself:—“But I must not omit to observe, that when these calculi were

* On the Urinary Organs, &c. pp. 100, 101.

entire, which was frequently the case, I could only ascertain the nature of the external surface, unless the layer contiguous to this presented spots sufficiently uncovered to admit of being examined*."

As a lithic nucleus prevails even with the phosphates—for when sawn through, and thoroughly examined, a lithic or oxalate of lime nucleus is generally found—a large proportion of the calculi examined by Brande and Dr. Marcet, and arranged by them under the head of the phosphates, probably are formed upon a lithic or oxalate of lime nucleus; and therefore perhaps would more strictly be referrible to the alternating class. Dr. Henry found only four instances out of the hundred and eighty-seven which he examined, the entire composition throughout being exclusively the earthy phosphates. Mr. Smith found twenty to consist principally of the phosphates. From all the observations and facts which have been collected, it would appear that the proportion of calculi composed essentially of the phosphates has been estimated much too high; and the ratio of those composed wholly of the phosphates is indeed extremely small.

The alternating calculi are, indeed, extremely important, because it points out to us the different transitions, as well as the order of succession, which generally prevails. From the table, it appears that one hundred and eighty-six of the whole were of this description, which is somewhat less than one-fourth, and rather more than one-fifth. Were we, however, to take this average, we should be greatly in error as to the real facts. If the particulars of the table be examined, it will be found that an unaccountable difference in the proportions prevails amongst the individual collections. Thus Brande found only five; the Norwich collection shews only nineteen; in Guy's only "six compound calculi in distinct layers" are mentioned; while Henry enumerates seventy-three under this head, and Mr. Smith eighty-three. These differences in all probability depend upon the different modes of arrangement adopted by the respective investigators. With respect, however, to the particulars, Dr. Marcet found fifteen calculi in which the lithic acid alternated with the oxalate of lime—a variety of which none of the other collections present a single instance. Dr. Prout gives a very interesting description of a calculus of this

sort. "He dissected a calculus," he says, "composed of lithic acid, oxalate of lime, and afterwards lithic acid again, with the view of ascertaining the transition from one species to the other. The change appeared to take place *ex abrupto*—that is to say, on the surface of the lithic calculus, which was a well-marked crystallized one; there was a very thin layer of a lighter colour, composed of lithic acid, lithate of ammonia, and oxalate of lime, intermixed; and upon this the oxalate of lime was immediately deposited in the crystallized state. The transition back again from the oxalate of lime to the lithic acid was still more abrupt, and absolutely without any perceptible intermediate state that I could observe; a plain proof that some time must have elapsed between the deposition of the different calculous matters. The oxalate of lime in this instance consisted of two distinct laminæ, the internal of which was beautifully crystallized in the form of rays perpendicular to the surface of the calculus, while the external consisted of a congeries of distinct crystals (some of them almost transparent), which rendered the external surface slightly rough and tuberculated*."

The next variety in our table is the mulberry and lithic, and we find the three first collections wholly destitute of it, not a single instance being mentioned; while in the Manchester it forms about one-seventeenth of the whole collection, and about a seventh of the Bristol. Again, we find the first three collections wholly deficient in the next variety—a very common one—the lithic and phosphates. At Manchester it constitutes between a fourth and fifth of the whole; and at Bristol about one in eighteen are stated to be of this description. Upon the transition from the lithic acid to the phosphates, Dr. Prout makes the following very valuable remarks:—"If," he says, "the calculus has originally been of the crystallized variety, the first symptom of change is commonly the disappearance of the crystallized character, and the substitution of the amorphous one in its stead; at the same time the colour becomes paler. These characters gradually increase till the fracture becomes perfectly amorphous, and the colour a pale clay brown, and very soon after this the phosphates begin to prevail entirely. These changes indicate that the transition from lithic acid to the phosphates takes place through the lithate of ammonia, and that it is accompanied by the disappearance of the usual colouring principle of the urine. It may, however," he continues, "be remarked that

* On Calculous Disorders, p. 115. Dr. Yelloly has since examined the entire collection at Norwich, consisting, if my recollection serves me right, of upwards of eight hundred calculi. His papers on this subject are published in the Philosophical Transactions, and may be consulted as affording some very valuable information upon this subject.

• On the Urinary Organs, p. 107.

we rarely meet with the above series of changes complete, the perfectly crystallized variety of lithic acid seldom passing to the phosphates; while on the contrary, the pale amorphous variety frequently passes into the phosphates, or contains them mixed*."

The alternation of the mulberry and phosphates is not found in the collections of these first columns, while in that of Manchester it forms an eleventh, and in the Bristol a seventh of the whole. And a difference even between these two collections is found, the mulberry species predominates in the Bristol, and the lithic in the Manchester.

It is rather singular that there should not be an instance of the alternation of the lithic mulberry and phosphate—an alternation by no means uncommon. In this plate 7, fig. 3, of Dr. Marcet's work, there is a very good representation of this description of calculi, in which you see first the lithic nucleus in *n*; next you see the tuberculated oxalate of lime in *m*; and lastly, the fusible covering externally in *f*.

The next varieties to which I shall direct your attention, are the fusible and lithic, and the fusible and mulberry. Of the first there appears but one, and of the second only two, making an aggregate of but three out of eight hundred and twenty-three, in which the phosphates were found surrounded or followed by other calculous deposits, a ratio of 1:274. Hence Dr. Prout deduces the very important law—that *a deposition of the mixed phosphates is never followed by any of the other depositions*. Dr. Prout has never seen any satisfactory exceptions to the universality of this law, and such exceptions as have presented might be readily explained. Thus, for instance, a small prostatic calculus escaping into the bladder and becoming a nucleus for the deposition of lithic acid, might thus present an apparent exception. Dr. Prout mentions an instance in which a prostatic calculus escaped into the bladder, and the urine was at the same time acid, and consequently had it contained an excess of lithic acid this would have been deposited upon the prostatic calculus, and have presented at least an apparent exception to the law. Dr. Marcet, in plate 8, fig. 8, gives the representation of an alternating calculus, in which all the species are found in concentric layers: first, the lithic nucleus is found in the centre; a layer of bone earth is next, which is surrounded by the oxalate of lime; and external to all is the fusible crust of mixed phosphates.

Now, upon a review of all these facts,

we gain some very important information. We find the lithic acid by far the most frequent urinary deposit; and that in a great majority of instances it forms the nuclei for the other species. Upon comparing the composition of calculi, we find them varying considerably from each other, both in their general characters and in the proportion of their constituents. But still we do not find so great a variety in the number of elements as that they cannot readily be reduced to a few, to which the composition of all calculi, in a practical and pathological point of view, may be conveniently limited. If we examine this matter we shall find that they may be reduced to four distinct principles, namely,

Lithic acid, and its salts or compounds.

Oxalate of lime.

Cystic oxide.

Earthy phosphates.

These Dr. Prout proposes to regard as constituting so many distinct and separate diatheses, as these principles are very seldom or never found in excess in the same urine at the same time. The lithic acid he places first in importance, not only because it constitutes the most frequent constituent of calculi, but also most frequently gives origin to the other species, by affording the primary nucleus around which the other calculous deposits composing them concrete.

The next in importance to the lithic acid is the oxalate of lime, as it appears to exhibit more decidedly the characters of an original diathesis, as it so frequently forms the nuclei of renal calculi. The cystic oxide is very rare; but as far as facts and observation enable us to infer, it is always of renal origin, and seems to exclude, when present, every other diathesis, as we shall have an opportunity of seeing when we come to consider the nature and characters of this diathesis. The phosphates naturally, indeed, come to be considered last. First, because they rarely constitute entire calculi; and while they succeed to the other diatheses, which, if protracted, invariably terminate in the phosphatic, yet the phosphates themselves are very rarely if ever followed by any of the other diatheses. The immediate cause of calculi is the deposition of the calculous principle by the urine which cannot retain it in solution. The circumstances which render the urine incapable of holding these principles in solution, and thus allowing their separation and deposition so as to form calculi, will probably be better considered under each particular diathesis; for, as the nature of the deposit varies, so will the condition of the urine, upon which the deposition depends, be found to vary in a corresponding degree.

LECTURES

ON THE

VENEREAL DISEASE,

Delivered at the Aldersgate School of Medicine,
March 1839,

By F. C. SKEY, F.R.S. &c.

LECTURE VI.

ON NON-VENEREAL SORES.

Herpes Preputialis.—Chronic form of the Disease. — Immediate and remote Causes. — *Psoriasis Preputialis.* — Cause. — Superficial Ulcerations of the Prepuce. — Resemblance to a Syphilitic Chancre. — Thickening of Prepuce preceding the appearance of the Ulcer. — Excoriation with or without Purulent Discharge or Gonorrhœa Preputii; occasionally confounded with true Gonorrhœa. — Operation for Phimosis, or removal of Prepuce by Excision. — Reference to previous Doctrines relative to the inapplicability of Mercurial Treatment in Ulceration. — Mercury an efficient Remedy in proportion as Ulceration is slow. — Bubo, Treatment of. — Necessity of selecting the most opportune moment for opening all Abscesses. — Treatment by Opium in Chronic Cases. — Mr. Hunter's Testimony to the Value of Treatment by Opium.

THE affections of the glans and prepuce, that, being situated on these surfaces, may be confounded with those of venereal origin, are herpes preputialis, psoriasis, superficial ulceration, superficial ulceration with thickening, partial excoriation, and extensive excoriation with purulent discharge, or gonorrhœa of the prepuce.

Herpes of the prepuce may appear on either surface of that fold, more generally perhaps on the inner. It consists in a crop of minute whitish vesicles, varying in number, from two or three to half a dozen; occupying a third or a fourth of the circumference, and acquiring as they advance an areola of inflammation. When seen early, they contain transparent lymph, which becomes puriform. They coalesce and form a thin scab: this separates and discloses an irregular ulcer, quite superficial. They are rarely attended with actual pain, but generally with an itching sensation; to relieve which, they are often subject to violence from rubbing. By such means the disease is aggravated, the prepuce becomes inflamed and œdematous, pain is felt along the track of absorbents on the dorsum, and bubo is no infrequent consequence. In this condition of the penis the surgeon is consulted, who, hastily observing the enlargement of the inguinal glands, the tumefaction of the prepuce, and the presence of a sore on the interior,

assures his patient that he is poxed. The patient contents himself with the declaration that he has had no promiscuous intercourse for twelve months previously. "Impossible!" exclaims the doctor; "I know better: a sore with bubo, and not venereal—you are surely mistaken." Positively the patient asserts that he has spoken the truth. "You may think so," replies the doctor, "but I cannot be mistaken in a case so unequivocally distinct, and you must, at all events, take mercury." Mercury is given, and the case improves, as it would have improved without. "Now," says the doctor, "you are convinced that I was right; I knew I could not be misled; this is all that is required to prove its venereal character, for you observe mercury has arrested it. I doubt not that it has saved your glans, to say nothing of your nose and palate, all of which might have fallen a sacrifice to the virulence of the poison." To carry this case on to another stage: suppose the gentleman, at any period within the next twelve months after his convalescence, to have sore throat after exposure to cold. "Here's a touch of our old enemy," says the same intelligent surgeon; "let us see the throat. Ah! unequivocally venereal. I could swear to that throat, that redness and swelling of the tonsils, that pain and difficulty of swallowing. Have you no eruption?"—"Positively none." The patient is subjected to another smart course of mercury, which may not materially protract his cure; and the doctor again enjoys the flattering unction, that his discrimination has saved from great suffering his deluded patient.

This doctrine has been severely reprobated, during the last fifteen or twenty years, by all reflecting practitioners. To conclude, because mercurial action or irritation effects a salutary influence on venereal ulcers, that *ergo* all diseases benefited by mercury are venereal, is on a par with the same argument applied to *iritis*—viz. that because one form of that disease, when coupled with syphilis, is amenable to treatment by mercury, therefore every form of *iritis* curable by mercury is syphilitic.

When herpetic disease of the prepuce has advanced—when it is attended by considerable tumefaction of the prepuce, and has finally assumed a chronic state—its aspect bears no apparent resemblance to the disease that produced it: the whole glans appears of a bright red colour from excoriation, and the prepuce has acquired a preternatural and fleshy thickness, which prevents its withdrawal behind the corona, or in which this object may be effected only with great difficulty. This is eczema of the penis, or rather of the glans and prepuce, and a disease very obstinate of cure.

The cause of herpes preputialis is simple local irritation, often occasioned remotely by disordered or disturbed action of the digestive system. It is often occasioned immediately by disordered or rather suspended action of the glandular bodies that surround the fossa glandis, following the continued action of stimuli prescribed for excessive secretion of those bodies. I have repeatedly known herpes caused by the daily application of irritating soap or stimulating injections, by which the action of the glands of the fossa was suspended, occasioning a preternatural dryness of the surface.

The treatment of herpes is very simple, and the more simple the better,—an aperient, and the frequent application of cold on the surface. If the prepuce be swollen, the attempt to retract it may excite irritation; and the cold application may be injected underneath the glans, and retained there for a few seconds, three or four times during every twenty-four hours. If exercise be imperative, care is required to prevent friction of the prepuce in walking; but it is better for the patient to remain quiet for a day or two. I recommend cold water; but a small quantity of lead (subacetate) may be added. When the scab has separated, the superficial ulcer then exposed will generally heal without difficulty; and it may be dressed with unguentum cetacei, or a much diluted citron ointment, or that of the oxide of zinc. In the more advanced stage the oxide of zinc ointment, diluted with an equal quantity of simple ointment, should be lightly rubbed over the whole surface, and retained for about twelve hours out of the twenty-four. It should be then removed by washing the surface with some unstimulating soap; and the smallest quantity of olive oil may be applied. The stimulus may be gradually increased as the disease recedes. I have occasionally used with advantage an ounce of olive oil to a drachm of spirits of wine.

Stimulants are very objectionable to that form of herpes which arises from suspended secretion of the glands which surround the fossa—the glandulæ odoriferæ. The evil is aggravated by too frequent cleansing. The natural secretion should be encouraged, and the glans may be lightly anointed with olive oil simply, which should be removed in twelve hours, otherwise it becomes rancid, and increases the evil. The oil may be removed by the application of dry lint, which is preferable to washing, and should then be re-applied.

Psoriasis Preputialis.

Psoriasis preputialis appears in the form of cracks around the margin, at-

tended by a degree of tumefaction of the prepuce: any attempt to withdraw the membrane aggravates the mischief, and occasions pain, often considerable. I confess I do not understand the ground on which this disease is named psoriasis. Psoriasis is classed by Willan among the squamæ, and consists in a desquamation of cuticle on an inflamed base of skin. Were it nothing more than a cutaneous disease, it would be difficult to explain the liability to bubo which occasionally attends it; but in reality it is something more. It is a disease involving the whole thickness of the prepuce, exhibiting deep chaps or clefts, which bleed on separating them, and the irritation of which causes some tumefaction. From its situation, the evil is often increased by the friction of the clothes. Inflammation of the prepuce is a natural consequence, accompanying the extension of the malady.

The treatment should be simple, and slightly stimulating. Mr. Evans recommends the Ung. Hydr. Nitr. somewhat diluted, than which I can tell you nothing better; but you will find it often very obstinate.

Psoriasis preputialis, when occurring in unhealthy constitutions, or when aggravated by the long-continued application of dirt, is an exceedingly obstinate disease. I have generally resorted to the continual application of a poultice, and found advantage from the use of black or yellow washes. It occurs in strumous habits not very rarely, and is often referred to the eccentric irritation of a stricture in the urethra. I doubt the truth of this suggestion, however. When this treatment is of temporary avail only, and the repetition of either this or the preceding malady becomes inveterate, it is very desirable that the prepuce should be removed, by which operation the liability to relapse is, to say the least, greatly diminished. For this purpose, it is not sufficient that the prepuce be merely divided, as adopted for the relief of phimosis, but the membrane must be removed; to accomplish which, it should be drawn forwards with some force, and cut off closely in front of the glans. A probe-pointed bistoury being then passed backwards should include the whole of the remaining fold, in order that the corona may be thoroughly denuded of its natural covering.

The prepuce is subject to the formation of small superficial ulcers, preceded by the slight itching of a pustule, which bursts without scabbing. Some persons are especially liable to them: they probably originate in a single vesicle instead of a cluster, as in herpes, which is more active in character than the latter disease, or this would probably form a scab. The ulcers

when first observed are very minute, and extend slowly till they become very distinct, having, however, no characters by which they may be distinguished from a slow venerola in the ulcerative stage, if we except the more determined progress of the latter. These ulcers may be single, or two or more may coalesce; but they always remain, however large in diameter, perfectly superficial. I have seen them again and again in persons perfectly free from all grounds of suspicion of a venereal contamination. Indeed, their birth, progress, and entire character, would belie the suspicion of any other than a simple cause. Sometimes these small ulcers, instead of spreading, will simulate the character of a real syphilitic chancre: they may acquire, not hardness, but positive thickening, which thickening shall be disproportionately large to the surface ulcerated. Again, the prepuce being retracted, will roll instead of being smoothly reverted, as, indeed, it always must, whenever its natural flexibility is destroyed by the deposition of lymph between its duplicature. Nay, the resemblance is so close, that we occasionally find the thickening preceding the ulcerative process, and it is often difficult to detect the precise spot on which the ulcer is situated. It is this fact that makes me doubt the specific character of the induration of syphilis, which I consider to be rather the nidus of disease than disease itself. I do not by this deny the specific nature of that disease, but that symptom only which is characterized by the indurated base, for I have repeatedly seen common sores on the penis attended by it.

This form of ulcer, whether accompanied with thickening or not, will always yield to ablation with cold water, the application of nitrate of silver, and moderate attention to the digestive system. The nitrate of silver should be very lightly applied to the ulcerated surface, and a dressing of spermaceti ointment laid upon it. Blue-stone is nearly as efficacious, but not quite. After which, the surrounding inflammation, whether limited, or extensive and involving the whole prepuce, rapidly subsides, and the ulcer, aided by a second or even a third application of the escharotic, heals. On what principle nitrate of silver acts in these and similar cases, I do not know—whether as an escharotic or merely as a stimulant. Much has been said on this subject: I am, for the present, contented to know that it and similar applications will cure the disease.

The absorbents are very liable to convey the irritation of these sores to the groin; but though I have seen many examples of enlarged glands accompanying them, I do not recollect to have seen one suppurate, nor, indeed, to advance far towards it.

Partial excoriation, and excoriation with purulent discharge or gonorrhœa of the prepuce and glans.

The partial excoriation, which appears in patches generally on the corona glandis, most frequently arises after sexual intercourse, as the result of mechanical friction on an unhealthy surface. The patches are somewhat circular, and present a livid colour, being mere abrasions of the cuticular surface of the glans and prepuce, from which, in the first instance, serum exudes. The locality of this simple form of injury appears unfavourable to the healing process, for the serum is often converted into pus, and the surface becomes floeculent, and then granular. The prepuce may become inflamed, and the ulcerative process extend within, when ordinary attention is withheld, and this not infrequently occurs in persons of the lower classes.

The sores should be washed with any mild stimulating lotion, as sulph. of zinc, 2 grs. to an ounce; or 1 gr. of sulph. of copper; or spirits of wine, ʒij. to ʒj. of water. If the surface be granular, a little of the flue of dry lint scraped should be applied after the lotion, and the whole surface cleansed of its secretion.

Excoriation of the corona and fossa is often the product of disease of the follicles of that region, the function of which, when considerably deranged, is repaired with difficulty. Its remote cause may be the application of irritating matter during connexion, or quite independently of such cause, it may arise from neglect of cleanliness, and appear spontaneously. It most frequently arises from neglect of a morbid condition of the sebaceous follicles (*glandulæ odoriferæ*), which may have existed for a longer or shorter period, which secrete a thick white pasty-looking matter, having a disposition to cake around the corona and fossa: at other times this secretion is soft, and of the consistence of cream. It is in this state of the parts that those extensive excoriations of the glans and of the prepuce occur, the secretion from which constitutes *gonorrhœa of the prepuce*. When extensive, it involves the interior of the prepuce, and spreads over a considerable portion of the glans, on denuding which a large tumefied surface is exposed, secreting moderately healthy pus, and presenting the raw excoriation which constitutes the disease. The whole prepuce becomes swelled, and a tendency to phimosis is a necessary consequence. In this condition, retraction of the membrane being difficult and painful, the endeavour to accomplish it is at length relinquished by the patient, and the disease may be mistaken for gonorrhœa; to which, on account of the often profuse discharge, the inflammation of the

prepuce with partial phimosis, and the enlargement of one or more inguinal glands, it bears considerable external resemblance. The important symptom of gonorrhœa, however, is wanting—viz. ardor urinæ, and by this alone may it be generally at once determined. Not that I think any patient of common intelligence who had been the subject of former gonorrhœa could mistake the requisite reply to the question, "Have you pain in making water?" But I have known instances to the contrary, where this appeared as the first occurrence of disease of the genital organs in young men. In hospital practice we often find these cases of very long standing; and what with the disease, and what with the extra stimulus of dirt, their diagnosis is not very easy.

Weak solutions of alum, of sulphate of zinc, dilutions of spirits of wine, all weak in proportion to the activity of the disease, will generally arrest it very speedily. An ordinary case may be cured in about 48 hours by either of these applications. When advanced, however, the exposure of the excoriated surface to the air, after washing with soap and water for a few minutes, will benefit it; and the lotion may be resorted to at the expiration of a few hours. After the surface has cicatrized, care should be taken to prevent its recurrence, by the daily application of a small quantity of olive oil, with a few drops of spirit, which should be renewed after about twelve hours' application. When inflamed, cold washes may be applied around the prepuce, and exercise prohibited; but this will not frequently be found necessary.

The diseases which I have just described are rarely found in persons whose glans are habitually denuded of the prepuce, in whom the cuticular lining of these surfaces becomes firm and dry, and consequently insusceptible of those forms of irritation which are the immediate product of the diseases in question. Some persons, although unaddicted to indulgence in women, are the almost perpetual subjects of one or other of these maladies, and in whom they are the fruitful parent of annoyance and expense. In such cases it were far preferable to adopt the only approach we can make to a radical cure, by removing as much of the prepuce as can be excised without danger to the glans in the operation; by which means the natural susceptibilities of the parts are destroyed, or rather removed, and the skin shortly acquires a condition very unfavourable to the repetition of the evil.

Before I leave this subject let me enjoin on you the necessity of personal observation in these matters. Do not be driven by authority to suppose all maladies of the

genitals must necessarily be venereal, because venereal disease first appears in that surface. Why should the glans penis, with its structure so peculiar, possess an immunity from disease from which the conjunctiva or the tonsils are not free? There is no reason why it should. You need not commit yourself by an opinion for some days. Watch the case for at least a week, unless it is phagedænic; you must then adopt more positive treatment; but depend upon it, the large majority of venereal sores are better let alone, as regards active treatment. You may always guard yourselves by stating that the sore will extend for some days, and perhaps reach three or four times its present size, before the ulcerative disposition will be exhausted, and that you will then treat it. Do not give mercury to arrest ulceration, for mercury will not arrest it. If you give mercury at all in ulceration, it is not for the ulceration, but for the poison which produces it; and then comes this important question—whether the ulceration is a direct consequence of the poison; for if it be not a direct consequence, mercury is not the treatment which either reason or experience will dictate. Very little observation is requisite to convince us, that the more active the ulcerative process, the less rapidly can we influence it by general means; and the means usually, but I maintain very inappropriately, employed to attain this end, is mercury. We do not use mercury for the ulceration, but for the cause of the ulceration, *i. e.* the supposed poison. Now the most rapid forms of ulceration occur in phagedænic disease—a disease which is often distinctly of spontaneous origin in certain conditions of health; and if not always spontaneous, probably communicable only to constitutions of its own kind. Where is the proof, then, of the presence of a poison to warrant the administration of mercury for its destruction? Phagedæna is an action, not a poison. Mercury has no other influence over the ulcerative stage of venerola than that of retarding it, while for the most part that of phagedæna is aggravated by it. In the indurated chancre, in which the ulcerative action is secondary, mercury is valuable; but then it does not act on the ulceration, but on the indurated base, from which the ulceration proceed, and that most torpidly. The process of ulceration is often held in check by syphilis, and the salutary influence of mercury may be tested by the ulcerative action being, as it were, let loose, for no sooner does the mercury exhibit itself in the system than the surface of the induration, when at all angular or exposed, breaks out into ulceration and gradually heals. I have observed this again and again in the indu-

rated frænum, which is rigid under the disease, but is destroyed by ulceration under the treatment. If we find, then, that mercury is advantageous in the torpid, that it is inefficient to any good purpose in the moderately active, and that it is actually injurious in the rapid forms of ulceration, may we not reasonably infer that, *quoad* venereal ulceration, mercury is not the antidote?

On Bubo.

I have a few words to say on the treatment of bubo, and they are as much in place here as in any other department of the subject, because nearly all that relates to it holds reference to the general principles of treating diseases, and not to either of the specific forms on which they attend; when present in phagedænic disease, they assume some of the characters of that form. I have already stated, that bubo by no means proceeds *pari passu* with the primary disease, but that it often advances for a time, and then recedes, although the sore extends uninterruptedly. Moreover, I have generally observed that the period of their often rapid subsidence, is that of the equally rapid increase of the primary sore. This applies, however, merely to the glandular swelling, and not to the open bubo. When the swelling suppurates, the wound then formed may partake of the character of the primary sore or not; but it will, under the most favourable circumstances, be more slow to assume healthy action, than any other form of bubo; often indeed, it becomes phagedænic, and the healing process is greatly protracted, after the original sore has cicatrized.

As a general rule the glandular swelling of the groin is not amenable to local treatment, until it exhibit symptoms of suppurative inflammation; and I think in all its early stages the less you interfere with it the better. If the primary disease be advancing in an unhealthy constitution—if the patient be unable to forego exercise of every description, and more especially when the surface becomes discolored by inflammation—it will in all probability suppurate. This propensity may sometimes be checked, by leeches, from 6 to 10 early and repeated, by absolute rest, and the application of cold, and to these may be added a brisk cathartic. But these agents will only effect a good result, when the activity of the bubo is on the wane, and when the consequent action is vacillating and uncertain in its course. If the suppurative inflammation be established, of which the best test in phlegmon is local pain, the above remedies will not only fail in the object, but will prove most hostile to the end in view. I often recommend the application of a few leeches for

the purpose of accelerating suppuration when at all protracted; but any considerable depletion will protract the suppurative stage, by raising a new and vicarious interest in the circulation at large.
